Nitric Oxide and Septic Shock

Hartmut Ruetten and Christoph Thiemermann

*The William Harvey Research Institute
St. Bartholomew's and the Royal London School of Medicine and Dentistry
London, United Kingdom*

NITRIC OXIDE (NO) IS GENERATED BY THREE DIFFERENT ISOFORMS OF NO SYNTHASE (NOS). TWO ISOFORMS ARE EXPRESSED CONSTITUTIVELY (IN ENDOTHELIUM, eNOS; IN BRAIN, nNOS), WHEREAS ONE IS INDUCED (iNOS) BY ENDOTOXIN OR CYTOKINES. EXPRESSION OF iNOS IN MANY ORGANS AND TISSUES IN SEPTIC SHOCK (CAUSED BY GRAM-NEGATIVE OR GRAM-POSITIVE BACTERIA) RESULTS IN AN ENHANCED FORMATION OF NO, WHICH CONTRIBUTES TO HYPOTENSION, VASCULAR HYPOREACTIVITY TO VASOCONSTRICTORS, AND POSSIBLY ORGAN INJURY/DYSFUNCTION AND HOST DEFENSE. INHIBITION OF THE EXPRESSION OF iNOS PROTEIN WITH, FOR EXAMPLE, DEXAMETHASONE, INHIBITORS OF THE ACTIVATION OF PROTEIN TYROSINE KINASES, OR INHIBITORS OF THE TRANSCRIPTION FACTOR NF- κ B, REDUCES THE CIRCULATORY AND MULTIPLE ORGAN FAILURE CAUSED BY ENDOTOXIN IN ANIMALS. ALTHOUGH ALL OF THESE INTERVENTIONS PREVENT THE EXPRESSION OF iNOS, THEY NEED TO BE GIVEN AS A PRETREATMENT (PRIOR TO THE ONSET OF SHOCK), AND THEY EXERT MANY OTHER EFFECTS (PREVENTION OF THE EXPRESSION OF OTHER PROTEINS) AND/OR SIDE EFFECTS. THIS CHAPTER REVIEWS THE EFFECTS AND SIDE EFFECTS OF VARIOUS INHIBITORS OF THE ACTIVITY OF NOS, WHICH CAN BE ADMINISTERED AT A STAGE WHEN HYPOTENSION HAS ALREADY DEVELOPED. THERE IS NOW GOOD EVIDENCE THAT INHIBITION OF iNOS ACTIVITY REDUCES THE HYPOTENSION CAUSED BY ENDOTOXIN OR SEPTIC SHOCK IN ANIMALS AND HUMANS. IN CONTRAST, INHIBITION OF eNOS ACTIVITY MAY LEAD TO EXCESSIVE VASOCONSTRICTION (ADVERSE EFFECTS). THERE IS LIMITED EVIDENCE REGARDING THE DEGREE OF iNOS INDUCTION IN CELLS/TISSUES OF HUMANS WITH SEPTIC SHOCK. DATA FROM CLINICAL TRIALS (PHASE III) INDICATE THAT NONSELECTIVE INHIBITORS OF NOS ACTIVITY [E.G., *N*^G-MONOMETHYL-L-ARGININE (L-NMMA)] DO NOT REDUCE MORTALITY IN PATIENTS WITH SEPTIC SHOCK.

An Introduction to the Pathophysiology and Therapy of Septic Shock

Septic shock is the life-threatening complication of an overwhelming systemic infection in which the immune system releases inflammatory mediators, resulting in pathophysiological vasodilation, hematological abnormalities, and organ dysfunction and failure. Sepsis affects 300,000–500,000 patients annually in the United States (Parrillo, 1989). The prevalence of sepsis in hospitalized patients has

significantly increased since the 1980s. Data from the National Hospital Discharge Survey of the Centers for Disease Control (1977–1987) show an increase in the discharge diagnosis of sepsis of 139% (*Morbidity and Mortality Weekly Report*, 1988). The increase was especially marked in patients over 65 years of age (162%). Despite improvements in intensive care management of critically ill patients, new antibiotics, and extensive research into the pathophysiology of sepsis, the mortality of septic shock still ranges from 20 to 55% (Dunn, 1987; Young, 1990). Most notably, mortality

increases to over 70% when shock is associated with multiple organ failure (Parker and Parrillo, 1983; Sprung *et al.*, 1984).

The first clinical presentation of sepsis often consists of fever, tachycardia, peripheral vasodilation, hypotension, and oliguria. However, the key symptom of shock is a severe fall in blood pressure, which is often associated with the dysfunction or failure of several important organs, including lung, kidney, liver, and brain. Despite the observed increase in cardiac output, blood pressure is not maintained because of excessive vasodilation. Treatment of septic shock includes respiratory support to optimize tissue oxygenation, intravenous fluid administration, broad-spectrum antimicrobial therapy, and vasopressor support.

The definition of septic shock is independent of the presence or absence of a multiple organ dysfunction syndrome (MODS), which is defined as impaired organ function such that homeostasis cannot be maintained without intervention (Baue, 1993). Primary MODS is a direct result of a well-defined insult to a specific organ. Secondary MODS occurs as a consequence of an exaggerated host response, termed systemic inflammatory response syndrome (SIRS). Approximately 75% of deaths from septic shock occur within hours to days after the onset of shock and are due to therapy-resistant hypotension, leading to the conclusion that peripheral vascular failure is the predominant factor determining outcome (Groeneveld *et al.*, 1988). The rest of the deaths occur days or weeks after the patient has recovered from hypotension, and the cause of death is multiple organ failure (Dal Nogare, 1991). Adult respiratory distress syndrome (ARDS), followed by renal and hepatic failure, is the most common sequence of events.

Septic shock is primarily initiated by components of the cell wall of gram-positive or gram-negative bacteria (Rietschel and Brade, 1992), but structural components of many other microorganisms generate a very similar biological response when they enter the circulation. Gram-positive organisms do not contain endotoxin (lipopolysaccharide or LPS), which is the cell wall component of gram-negative bacteria responsible for the initiation of septic shock. The cell wall of gram-positive bacteria contains lipoteichoic acid (LTA) and peptidoglycan (PepG). LTA is a macroamphiphile, containing a substituted poly(glycerophosphate) backbone attached to a glycolipid. PepG is a large polymer, which provides stress resistance and shape-determining properties to bacterial cell walls (Springer, 1990). LTA and PepG act in synergy to release tumor necrosis factor α (TNF- α) and γ -interferon, to induce iNOS (inducible nitric oxide synthase), and to cause shock and multiple organ failure in anesthetized rats (DeKimpe *et al.*, 1995). Interestingly, a specific fragment of PepG, namely, NAG-NAM-L-Ala-D-isoglutamine, is the moiety within the PepG polymer that acts synergistically with LTA to induce NO formation in macrophages (Kengatharan *et al.*, 1998). This moiety is also present in the PepG of the nonpathogenic bacterium *Bacillus subtilis*. Interestingly, LTA from *Staphylococcus aureus* but not that from *B. subtilis* works in synergy with PepG from either

bacterium. Thus, it has been proposed (Kengatharan *et al.*, 1998) that it is the structure of LTA which determines pathogenicity, whereas PepG amplifies the response to LTA.

Cytokines and Septic Shock

Cytokines are a heterogeneous group of hormonelike proteins, produced by all organs and many cell types, that establish a communication network between various cells of each organ. Activation of the cytokine network follows a lag phase and is preceded by the activation of, for example, the complement and kallikrein system. The study and the understanding of the cytokine network in septic shock is complicated by the following factors: (1) cytokines often induce the secretion of additional cytokines; (2) cytokines modulate each other's actions, resulting in additional, synergistic, or inhibitory effects, or even a novel effect not seen with individual cytokines alone; (3) the sequence of cytokine exposure can influence the response of a specific target cell; and (4) the effects of cytokines may be dose-related, with quantitatively different biological effects seen at different doses (Deutsch, 1992).

The proinflammatory cytokines TNF- α and interleukin-1 β (IL-1 β) have been implicated in the pathophysiology of many cardiovascular disorders, including circulatory shock (Okusawa *et al.*, 1988; Tracy, 1991; Billiau and Vandekerckhove, 1991; Mozes *et al.*, 1991; Hewett *et al.*, 1993; Dinarello, 1996). Administration of TNF- α alone or in combination with low doses of endotoxin mimics several features of the pathophysiology of circulatory shock, including hypotension and organ injury (Tracy, 1991; Billiau and Vandekerckhove, 1991). Intravenous administration of IL-1, either alone or in combination with low doses of LPS or TNF- α , also produces a shocklike state (Okusawa *et al.*, 1988). Pronounced rises in the serum levels of TNF- α and IL-1 β occur in experimental endotoxemia (Beutler *et al.*, 1985) and in humans with sepsis and septic shock (Friedland *et al.*, 1996; Stuber *et al.*, 1996). Higher concentrations of TNF- α and IL-1 β are associated with an increase in the risk for ARDS, MODS, and death (Roumen *et al.*, 1993). Antibodies directed against TNF- α or IL-1 β exert protective effects in various animal models of endotoxin shock (Tracy *et al.*, 1987; Wakabayashi *et al.*, 1991).

Nitric Oxide and Septic Shock

Discovery of the Role of Nitric Oxide in the Pathophysiology of Shock

In July of 1990, Thiemermann and Vane reported that the acute hypotension caused by injection of endotoxin into the rat was attenuated by intravenous infusion of the nitric oxide synthase (NOS) inhibitor *N*^G-monomethyl-L-arginine (L-NMMA) (1 mg/kg/min i.v. for 20 min). This beneficial effect of L-NMMA was reversed by L-arginine (6 mg/kg/min

i.v. for 20 min). One could argue that the increase in blood pressure [due to inhibition of endothelial NOS (eNOS) activity] afforded by infusion of L-NMMA may be sufficient to cause a functional antagonism of any hypotensive effect of endotoxin. This is, however, unlikely, as an infusion of the α_1 -receptor agonist phenylephrine (in a dose that caused a degree of hypotension similar to that produced by L-NMMA) did not affect the fall in blood pressure caused by endotoxin in the anesthetized rat. The authors, therefore, proposed that a stimulation of the formation of NO contributes to the endotoxin-induced hypotension *in vivo* (Thiemermann and Vane, 1990). In November of the same year, Kilbourn and colleagues (1990) reported that a single injection of L-NMMA (20 mg/kg i.v. at 1.5 min after endotoxin) reversed the acute fall in blood pressure and peripheral vascular resistance caused by injection of endotoxin in the anesthetized dog. Although L-NMMA caused a pressor effect in dogs without endotoxemia, the increase in blood pressure afforded by the NOS inhibitor in dogs with endotoxemia was significantly greater than in the respective control animals. In addition, L-NMMA did not reduce the hypotension caused by an organic nitrate (glyceryl trinitrate). These findings again suggested that endotoxin stimulates the formation of NO, which in turn contributes to the hypotension afforded by this wall fragment of gram-negative bacteria (Kilbourn *et al.*, 1990). Taken together, these two studies suggested that inhibitors of NOS activity may be useful in the therapy of the severe hypotension in septic shock.

One key feature of the severe hypotension in septic shock was the, then unexplained, phenomenon that this hypotension is difficult to overcome by infusion of vasopressor agents such as norepinephrine. Although this "vascular hyporeactivity" or "vasoplegia" had been known for a long time, the underlying pathology was unknown. In a series of elegant studies published between September and November of 1990, the group of Dr. Stoclet (Strasbourg, France) reported that the vascular hyporeactivity caused by endotoxin *in vitro* and *in vivo* was also secondary to and enhanced formation of NO. For instance, incubation of (endothelium-denuded) rat aortic rings for 5 hours with endotoxin attenuated the vasoconstrictor response elicited by norepinephrine. Inhibition of the activities of NOS and guanylate cyclase with L-NMMA and methylene blue restored the contractile responses to norepinephrine. The observed effect of L-NMMA was reversed by L-arginine but not by D-arginine. Thus, the hyporeactivity to norepinephrine caused by endotoxin in vascular smooth muscle is secondary to activation both of the L-arginine pathway and of soluble guanylate cyclase (Fleming *et al.*, 1990). Similarly, the vascular hyporeactivity to calcium was also attenuated by L-NMMA in an L-arginine-reversible fashion (Gray *et al.*, 1990). Most notably, L-NMMA restored the pressor responses to norepinephrine in rats subjected to endotoxemia *in vivo* (Julou-Schaeffer *et al.*, 1990). The impairment of the contractile responses elicited by phenylephrine in rat aortic rings obtained from rats subjected to endotoxemia was attenuated by NOS inhibitors, cycloheximide, and glucocorticoids, suggesting that the ob-

served overproduction of NO is secondary to the induction of iNOS in the vasculature (Rees *et al.*, 1990). An enhanced formation of NO by eNOS (endothelium) and iNOS (vascular smooth muscle) contributes to the early and late hypotension (Szabo *et al.*, 1993) as well as the vascular hyporeactivity to vasoconstrictor agents caused by endotoxin *in vivo*. We now know that the circulatory failure associated with the administration of TNF- α (Kilbourn *et al.*, 1990) and IL-2 (Kilbourn *et al.*, 1994) and with hemorrhagic shock (Thiemermann *et al.*, 1993), gram-positive shock (De Kimpe *et al.*, 1995; Kengatharan *et al.*, 1998), and traumatic shock (Szabo and Thiemermann, 1995) is, at least in part, due to an enhanced formation of NO by iNOS. Taken together, these studies form the basis of the hypothesis developed between 1990 and 1993 that agents which reduce the formation of NO (particularly by iNOS) may be useful to overcome the "therapy-refractory" circulatory failure observed in patients with shock of different etiologies. This conclusion is supported by the discovery that mice deficient in iNOS (iNOS knockout mice) exhibit only a minor fall in blood pressure when challenged with endotoxin (MacMicking *et al.*, 1995; Wei *et al.*, 1995). Most of the results published between 1990 and 1995 supported the view that reducing the enhanced formation of NO (e.g., by iNOS) may become a useful therapeutic approach in sepsis/septic shock. In principle, there are two approaches to achieve this goal, namely, inhibition of iNOS induction and/or inhibition of the activity of iNOS by inhibiting the enzyme itself or one of its cofactors.

Inhibition of the Induction of iNOS in Experimental Endotoxemia

The mechanism of iNOS induction is not fully understood. It clearly involves the transcription of mRNA and novel protein biosynthesis. Sequencing of the DNA regions upstream of the NOS gene (i.e., the promoter region) revealed separate promoter regions for the induction of iNOS by LPS and γ -interferon (Xie *et al.*, 1993). There is increasing evidence for the involvement of the nuclear transcription factor NF- κ B (Sherman *et al.*, 1993; Mulsch *et al.*, 1993; Griscavage *et al.*, 1995), tyrosine kinase activation (Dong *et al.*, 1993; Marczin *et al.*, 1993; Kengatharan *et al.*, 1996), microtubule depolymerization (Marczin *et al.*, 1993), and protein kinase C ϵ (Diaz-Guerra *et al.*, 1996) in the induction process (Fig. 1).

Induction of iNOS can be inhibited by numerous agents including glucocorticoids (Radomski *et al.*, 1990), thrombin (Schini *et al.*, 1992), ethanol (Militante *et al.*, 1997), as well as macrophage deactivation factor and transforming growth factor β , platelet-derived growth factor, endothelin-1, IL-4, IL-8, IL-10, and IL-13 (Green and Nacy, 1993; Schneemann *et al.*, 1993; Doyle *et al.*, 1994; Hirahashi *et al.*, 1996; Saura *et al.*, 1996). Inhibitors of protein kinase C (Okuda *et al.*, 1997), inhibitors of protein tyrosine kinase (Kengatharan *et al.*, 1996; Salzman *et al.*, 1996; Joly *et al.*, 1997), or inhibitors of the activation of NF- κ B (Xie *et al.*, 1994; Griscavage *et al.*, 1995; Kengatharan *et al.*, 1996; Schini-Kerth *et al.*,

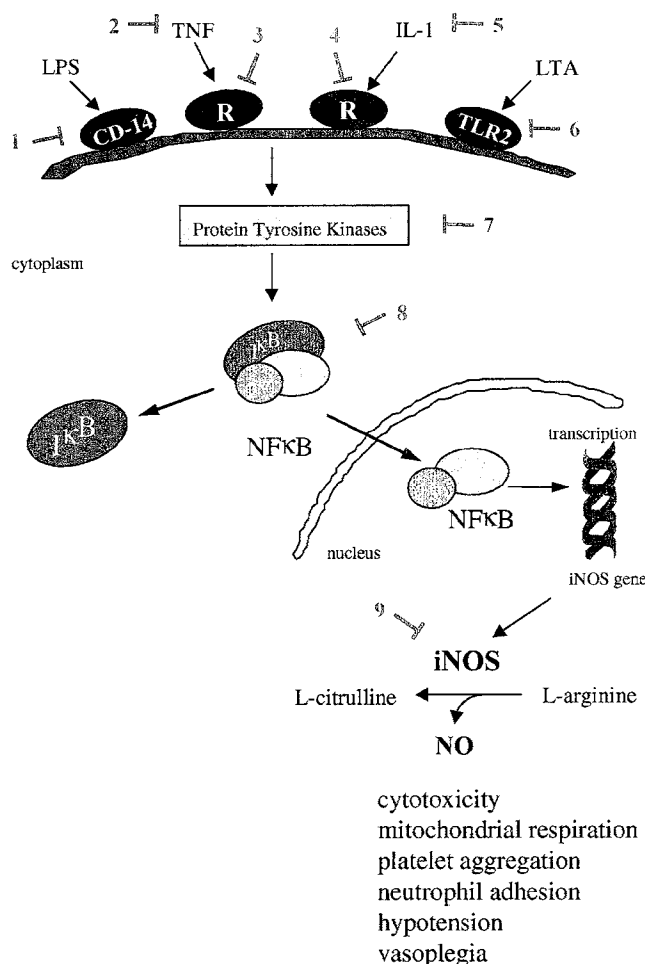

Figure 1 Hypothetical signal transduction pathway leading to the induction of iNOS and possibilities for reduction of NO formation. Possibilities to reduce NO formation include the following: 1, CD-14 antibody; 2, tumor necrosis factor- α (TNF) antibody; 3, TNF α receptor antagonist; 4, interleukin-1 β (IL-1 β) receptor antagonist; 5, IL-1 β antibody; 6, toll-like receptor 2 (TLR2) receptor antagonist; 7, protein tyrosine kinase inhibitors (e.g., genistein, tyrphostins); 8, inhibitors of the activation of the nuclear transcription factor NF- κ B [e.g., pyrrolidine dithiocarbamate (PDTTC), dexamethasone, calpain inhibitor-1]; 9, inhibitors of iNOS activity [e.g., N^G -methyl-L-arginine (L-NMMA), aminoguanidine, aminoethyl-isothiourea (AE-ITU)].

1997) can also inhibit the induction of iNOS. An increase in cAMP induces iNOS in vascular smooth muscle cells and rat renal mesangial cells (Koide *et al.*, 1993; Kunz *et al.*, 1996), whereas prolonged elevation of intracellular cAMP levels in macrophages inhibits iNOS induction (Bulut *et al.*, 1993). NO itself can also regulate its activity, both by inhibiting iNOS activity (Assreuy *et al.*, 1993) and by downregulating iNOS mRNA (Nussler and Billiar, 1993). It should be noted that some of the above interventions (e.g., inhibitors of the activities of protein tyrosine kinases and of NF- κ B) will also prevent the expression of many other genes. Thus, it is impossible to determine if, and to what extent, the reported beneficial effects of tyrosine kinase inhibitors (Novogrodsky *et al.*, 1994; Vanichkin *et al.*, 1996; Ruetten and Thieme-

mann, 1997a), IL-10 (Gerard *et al.*, 1997), IL-13 (Mucha-muel *et al.*, 1997; Nicoletti *et al.*, 1997), and dexamethasone (Wright *et al.*, 1992; Ruetten and Thieme-mann, 1997a) and of inhibitors of NF- κ B (Ruetten and Thieme-mann, 1997b; Liu *et al.*, 1999) in animal models of shock are due to the prevention of iNOS induction (Figs. 2 and 3). The molecular mechanism by which dexamethasone exerts beneficial effects in endotoxin shock is not well understood, but there is evidence that glucocorticoids inhibit the action of the transcription factors AP-1 (activator protein 1) and NF- κ B (Barnes and Karin, 1997). For instance, a protein-protein interaction between the activated glucocorticoid receptor and NF- κ B, resulting in prevention of its binding to the κ B consensus motif on the promoter of its target genes, has been reported. In addition, glucocorticoids enhance the formation of I κ B α , which results in an excess of this inhibitory factor in the nucleus and cytosol. Thus, activated NF- κ B, when “traveling” to the nucleus, meets with and binds to I κ B to form its “dormant” (inactive) cytosolic form (for a detailed review, see Barnes and Karin, 1997). Agents that selectively prevent the expression of iNOS or result in the expression of an inactive protein are currently being developed.

It should be stressed that all of the above interventions must be administered prior to the application of endotoxin or at least prior to the induction of iNOS to exert beneficial effects in animal models of shock. For instance, the administration of dexamethasone, calpain inhibitor I, or tyrosine kinase inhibitors to rats at 2 hours after the injection of endotoxin neither exerts beneficial effects on hemodynamic or organ injury nor inhibits the induction of iNOS (Wright *et al.*, 1992; Paya *et al.*, 1993; Ruetten and Thieme-mann, 1997a, b) (Figs. 2 and 3). Similar to the clinical administration of antibodies against proinflammatory cytokines, the timely administration of inhibitors of the induction of iNOS will be crucial to achieve beneficial effects in patients with severe sepsis. Practically, one needs to determine the time between the induction of iNOS (or early phases of the syndrome) and the administration of the inhibitors of iNOS induction. This supports the view that drugs that directly inhibit iNOS activity are more likely to exert beneficial effects in the therapy of septic shock than agents that inhibit the induction of iNOS. The latter compounds may, however, be used in chronic conditions (e.g., of an inflammatory nature) in which iNOS has been reported to play a role.

Inhibition of NOS Activity: Effects and Side Effects in Animals with Septic Shock

Although there is good evidence that endotoxemia or sepsis in rodents results in the induction of iNOS (in various tissues), leading to an increase in the plasma levels of nitrite/nitrate (from 20 up to 600 μ M), there is limited information regarding the time course of iNOS induction, the degree of iNOS activity (in tissues), or even the plasma levels of nitrite/nitrate in large animal models (pig, dog, sheep, baboon) of shock or in humans with sepsis and septic shock. Clearly, sepsis (or endotoxemia) results in an increase in the plasma

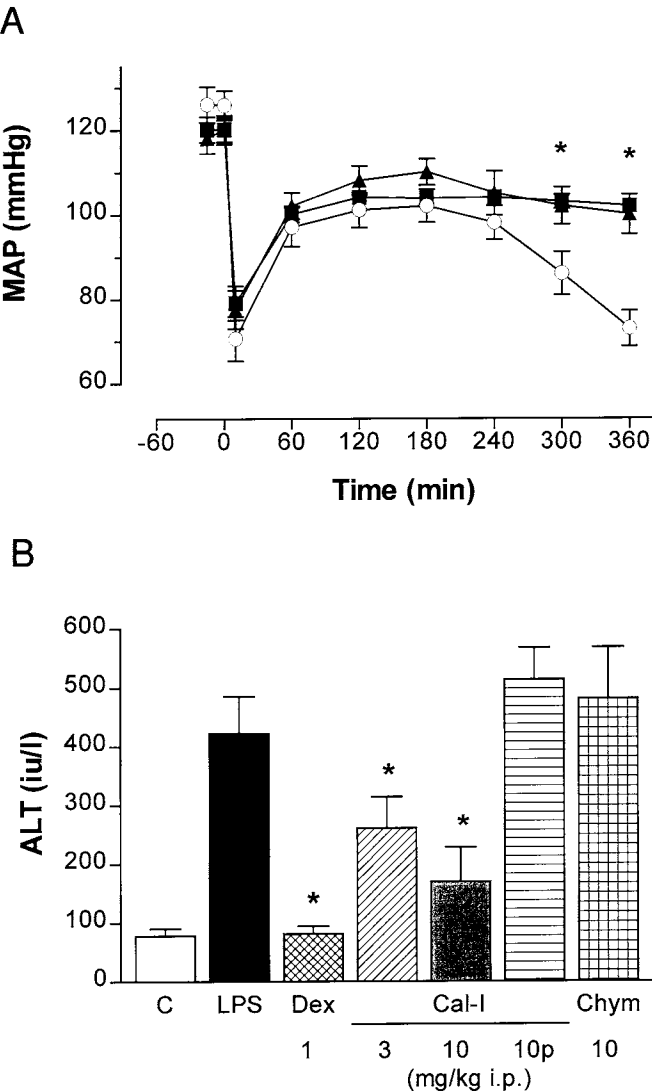

Figure 2 Calpain inhibitor I or dexamethasone prevent (A) the delayed circulatory failure (fall in mean arterial blood pressure; MAP) and (B) liver failure (increase in alanine aminotransferase; ALT) in rats with septic shock. Different groups of animals received vehicle for *Escherichia coli* lipopolysaccharide (LPS) (C, $n = 4$), LPS alone (LPS, 10 mg/kg i.v., $n = 10$, open circles), LPS plus 1 mg/kg i.p. dexamethasone (Dex, $n = 6$; filled squares), LPS plus 3 mg/kg i.p. of calpain inhibitor I (Cal-I, 3; $n = 6$), LPS plus 10 mg/kg i.p. of calpain inhibitor I (Cal-I, 10; $n = 7$, filled triangles), LPS plus late administration at 2 hours after LPS of 10 mg/kg i.p. of calpain inhibitor I (Cal-I, 10p; $n = 4$), or LPS plus chymostatin (Chym; $n = 5$). Data are expressed as means \pm SEM of n observations. $*p < 0.05$ represents significant difference when compared to LPS controls.

levels of nitrite/nitrate in these species. Thus, when evaluating the role of NO or elucidating the effects of NOS inhibitors in animal models of shock, one needs to consider that (i) many of the models used are acute, nonresuscitated, hypodynamic models of shock, (ii) the effects (and side effects) of nonselective inhibitors of NOS activity will greatly vary depending on the degree of iNOS induction in the species, and (iii) any observed effects of the respective NOS inhibitor used will obviously depend on the chosen dose regimen and timing of the intervention (Table I).

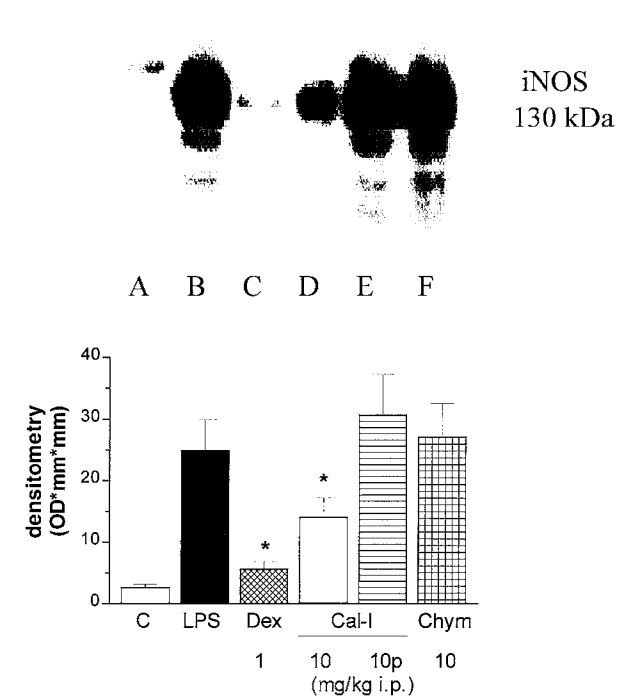

Figure 3 Effect of calpain inhibitor I on the expression of iNOS protein in lung homogenates at 6 hours after administration of endotoxin. Different groups of animals received vehicle (C) for *E. coli* lipopolysaccharide (LPS; lane A), LPS alone (LPS; lane B), LPS plus 1 mg/kg i.p. dexamethasone (Dex; lane C), LPS plus 10 mg/kg i.p. of calpain inhibitor I (Cal-I; lane D), LPS plus late administration at 2 hours after LPS of 10 mg/kg i.p. of calpain inhibitor I (Cal-I; lane E), or LPS plus chymostatin (Chym; lane F). Similar results of the Western blots were seen using tissue extracts from two other animals with the same treatment. $*p < 0.05$ represents significant difference when compared to LPS controls.

L-NMMA AND OTHER ANALOGS OF L-ARGININE

Inhibition of iNOS activity can be achieved with competitive inhibitors of NOS enzyme activity. The discovery of L-arginine analogs that inhibit NOS activity, including L-NMMA, provided the first tool to explore the beneficial or side effects of NOS inhibitors in animals and humans with septic shock. The subsequent discovery of the NOS

Table I Possible Effects of Administration of NOS Inhibitors in Septic Shock

Beneficial effects	Adverse effects
Increased blood pressure	Excessive vasoconstriction
Restores responsiveness to pressor agents	Pulmonary hypertension
Cardiac output return to baseline values	Fall in cardiac output
Decreased production of peroxynitrite	Increased platelet adhesiveness
Attenuation of inhibition of mitochondrial respiration	Increased neutrophil adhesion
Improved organ function	Worsened organ function
Improved survival	Reduction in survival

inhibitors *N*^G-nitro-L-arginine (L-NA) and its methyl ester (L-NAME; Moore *et al.*, 1990), which in contrast to L-NMMA were inexpensive and readily available, stimulated numerous studies aimed at evaluating the role of NO in septic shock by using (high doses of) L-NAME. This was somewhat unfortunate, as L-NAME is a more potent inhibitor of eNOS than iNOS activity. Thus, L-NAME caused many adverse effects resulting from the inhibition of eNOS activity, including excessive vasoconstriction with a fall in cardiac output, pulmonary hypertension, and enhanced adhesion of platelets and neutrophils to the endothelium. Thus, it was not surprising that high doses of L-NAME or L-NMMA increased mortality in mice and rabbits with endotoxic shock (see Thiernemann, 1994, for review). The hypothesis that the basal release of NO by eNOS has an important role in the regulation of regional blood flow (beneficial effects of NO), while the excessive generation of NO by iNOS “in the wrong place at the wrong time” contributes to some aspects of the pathophysiology of shock (harmful effects of NO), has stimulated the search for selective inhibitors of iNOS activity (Fig. 4).

AMINO GUANIDINE

Aminoguanidine was the first relatively selective inhibitor of iNOS activity discovered (Corbett *et al.*, 1992; Nilsson, 1999). Although aminoguanidine is a more potent inhibitor of iNOS than eNOS activity *in vitro* and *in vivo* (Misko *et al.*, 1993; Wu *et al.*, 1995), aminoguanidine is not a very potent inhibitor of iNOS activity (IC_{50} , approximately 100–150 μM). In addition, aminoguanidine is not a very specific inhibitor of iNOS activity, as this guanidine has many other pharmacological properties, including inhibition of (1) histamine decarboxylase, (2) polyamine catabolism, (3) the formation of advanced glycosylation end products, and (4) catalase activity (Wu *et al.*, 1995). Interestingly, aminoguanidine also prevents the expression of iNOS protein by a hitherto unknown mechanism (Ruetten and Thiernemann, 1996). Thus, aminoguanidine (like aminoethyl-isothiourea, see later) has to be regarded as an agent which affects iNOS activity by two distinct mechanisms, namely, prevention of the expression of iNOS protein and inhibition of iNOS activity.

S-SUBSTITUTED ISOTHIUREAS

S-Substituted isothioureas (ITUs) are non-amino acid analogs of L-arginine and also potent inhibitors of iNOS activity with variable isoform selectivity (Garvey *et al.*, 1994; Szabo *et al.*, 1994; Southan *et al.*, 1995). The most potent isothioureas are those with only short alkyl chains on the sulfur atom and no substituents on the nitrogen atoms. For instance, S-ethyl-ITU is a potent competitive inhibitor of human iNOS, eNOS, and nNOS (brain NOS) activity. In contrast to S-ethyl-ITU, aminoethyl-ITU, and S-methyl-ITU are more selective inhibitors of iNOS than of eNOS activity *in vitro* and *in vivo* (Southan *et al.*, 1995). Interestingly, aminoethyl-ITU is metabolized to mercaptoethyl-guanidine (and possibly to the isothiourea 2-aminothiazoline), which

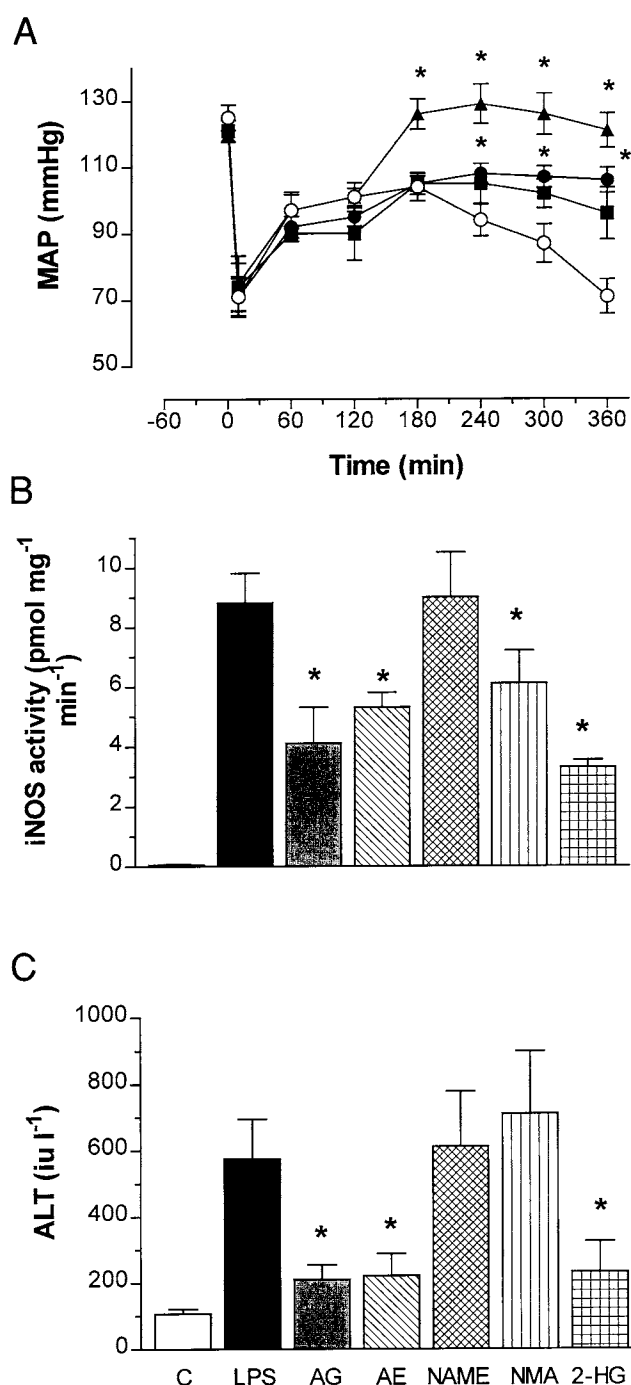

Figure 4 (A) Effect of aminoguanidine (AG, $n = 8$; filled squares), aminoethyl-isothiourea (AE, $n = 8$; filled circles), or *N*^G-nitro-L-arginine methyl ester (L-NAME, $n = 6$; filled triangles) on the fall in mean arterial blood pressure (MAP) caused by *E. coli* lipopolysaccharide (LPS; 10 mg/kg i.v.) in the anesthetized rat. The alterations in MAP (over time) of rats that were pretreated with vehicle (for the drugs) and then received LPS are also shown (LPS control, $n = 10$; open circles). (B) Effect of different NOS inhibitors on the increase in iNOS activity and (C) the serum concentration of alanine aminotransferase (ALT) in rats with septic shock. Different groups of LPS rats were infused for 4 hours with vehicle ($n = 10$), AG ($n = 8$), AE ($n = 8$), *N*^G-nitro-L-arginine methyl ester (NAME, $n = 6$), *N*^G-methyl-L-arginine (NMA, $n = 6$), or 1-amino-2-hydroxy-guanidine (2-HG, $n = 10$). The infusion of drug or vehicle was started at 2 hours after LPS. Data are expressed as means \pm SEM of n observations. * $p < 0.05$ represents a significant reduction in concentration/activity when compared to LPS rats.

may represent the active principle of aminoethyl-ITU. Indeed, mercaptoalkyl-guanidines, in particular mercaptoethyl- and mercaptopropyl-guanidines, are the most potent (guanidino) inhibitors of iNOS activity (see Southan and Szabo, 1996 for review).

AMIDINES

S-Substituted ITUs and guanidines contain the amidine function [$-\text{CH}(-\text{NH})\text{NH}_2$], a feature that they have in common with O-substituted isoureas and amidines themselves. Indeed, amidines including 2-iminopiperidine, butyramidine, 2-aminopyridine, propioamidine, and acetamidine inhibit NOS activity. Interestingly, both 2-iminopiperidine and butyramidine are more potent inhibitors of iNOS activity than L-NMMA in murine macrophages. Recently, an analog of acetamidine termed 1400W [N -[3-(aminomethyl)benzyl]acetamidine] has been reported to be a slow, tight-binding inhibitor of human iNOS. The inhibition by 1400W of the activity of human iNOS was (1) extremely potent, (2) dependent on the cofactor NADPH, and (3) either irreversible or extremely slowly reversible. Most notably, 1400W was approximately 5000-fold more potent as an inhibitor of iNOS activity than of eNOS activity. Moreover, the inhibition by this agent of the activity of eNOS or nNOS activity was reversible by L-arginine, whereas iNOS inhibition was not. In a rat model of vascular injury caused by endotoxin, 1400W was 50-fold more potent as an inhibitor of iNOS than eNOS activity (Garvey *et al.*, 1997). Thus, 1400W appears to be the most potent and selective inhibitor of iNOS activity known to date and, hence, will be an ideal tool to elucidate the role of NO from iNOS in shock and other diseases associated with the induction of iNOS.

We have more recently discovered that 1400W (3–10 mg/kg/hour) attenuates both iNOS activity as well as the delayed hypotension caused by endotoxin in the rat in a dose-related fashion. Most notably, infusion of 10 mg/kg/hour of 1400W (starting 2 hours after endotoxin) abolished both the increase in nitrite-plus-nitrate as well as the delayed hypotension caused by LPS. These beneficial hemodynamic effects of 1400W did not, however, translate into a protection of organs such as the kidney, liver, and pancreas against the multiple organ injury caused by endotoxin in the rat. These results suggest that an enhanced formation of NO from iNOS contributes to the circulatory failure but not the organ dysfunction associated with endotoxic shock (Wray *et al.*, 1998). In addition to exerting beneficial effects in animal models of shock, 1400W also reduces the tissue injury caused by ischemia–reperfusion of the brain (Parmentier *et al.*, 1999).

Reduction of NO Formation: Effects and Side Effects in Patients with Septic Shock

Although our understanding of the role of NO in animal models of circulatory shock has improved substantially over

the past years, our knowledge regarding the biosynthesis and importance of NO in the pathophysiology of patients with shock (of various etiologies) is still very limited. Indeed, a Medline search covering the period from 1987 to November 1995 revealed that only 8 to 14% of all of the publications which included the key term “nitric oxide” also included the key word “human” (Preiser and Vincent, 1996). What, then, is the evidence that septic shock in humans is associated with an enhanced formation of NO? Elevated plasma and urine levels of nitrite plus nitrate have been reported in adults and children with severe septic shock as well as in patients with burn injuries who subsequently developed sepsis. Moreover, elevated plasma levels of nitrite plus nitrate occur in patients receiving IL-2 chemotherapy. In contrast, there is also evidence that the plasma levels of nitrite plus nitrate are lower in patients after trauma, surgery, and in patients with HIV infections (see Preiser and Vincent, 1996). Interestingly, the increase in iNOS activity in leukocytes obtained from patients with sepsis appears to correlate with the number of failing organs but not with blood pressure. Taken together, these studies support the conclusion that septic shock in humans is associated with an enhanced formation of NO. It should, however, be stressed that the increase in the plasma levels of nitrite plus nitrate elicited by endotoxin, cytokines, or bacteria in rodents (10-fold) is substantially higher than the observed increases in the plasma levels of these metabolites of NO in other animal species (pig, sheep, etc.) or humans. Moreover, our understanding of (i) the biosynthesis of NO, (ii) the regulation of and the mechanism involved in the expression of iNOS, and (iii) the role of NO in MODS in shock are largely based on animal experiments of endotoxic shock in rodents. In contrast, we know relatively little about the role of NO in patients with septic and other forms of circulatory shock.

There is evidence that endotoxin and cytokines (TNF- α , IL-1, and γ -interferon, when given in combination) cause the expression of iNOS as well as the formation of NO in various human cells (primary or cell lines), including hepatocytes, mesangial cells, retinal pigmented epithelial cells, and lung epithelial cells (Morris and Billiar, 1994; Preiser and Vincent, 1996). Interestingly, IL-1 causes the hyporeactivity of human hand veins (*in situ*) to the constrictor effects elicited by exogenous or endogenous norepinephrine, and this vascular hyporeactivity is largely attenuated by L-NMMA, suggesting that it is mediated by NO (P. Vallance, personal communication). Although the clinical trials aimed at reducing the effects of TNF- α and IL-1 in patients with septic shock were not designed to prevent the formation of NO, some of the key findings of these trials are summarized in the following paragraph.

There is no convincing evidence that interventions aimed at reducing the effects of TNF- α (e.g., antibodies against TNF- α , soluble TNF α receptors) cause a significant reduction in 28-day mortality in patients with septic shock (Abraham *et al.*, 1995; Dhainaut *et al.*, 1995; Cohen and Carlet, 1996; Reinhart *et al.*, 1996). Most notably, there is one report documenting that the treatment of septic patients

with the TNF receptor:Fc fusion protein causes a dose-related increase in mortality (Fisher *et al.*, 1996). Similarly, clinical trials evaluating the effects of the IL-1 receptor antagonists have not resulted in a significant reduction in 28-day mortality (Fisher *et al.*, 1994; Knaus *et al.*, 1996). Although the trials failed to provide evidence that any of the anticytokine interventions used caused a significant reduction in 28-day mortality, these studies nevertheless support the view that both TNF- α as well as IL-1 play a role in the pathophysiology of septic shock and indicate that anticytokine therapy may well be of benefit for certain groups of patients. The IL-1ra Phase III Sepsis Syndrome Group has reported that (i) there is a direct relationship between the predicted risk of mortality of a patient at study entry and the efficacy of the IL-1 receptor antagonist (IL-1ra) in that (ii) patients with a predicted risk of mortality of $<24\%$ derived little benefit, whereas (iii) IL-1ra reduced the risk of death in the first 2 days for patients with a predicted risk of mortality of $>24\%$ (Knaus *et al.*, 1996). There is, however, some evidence that the prevention of the formation of both TNF- α and IL-1 β (e.g., with γ -interferon or IL-10) is superior to prevention of the formation of either one of these cytokines in reducing mortality in rodent models of endotoxemia (Smith *et al.*, 1993). Moreover, the reduction in survival afforded by a combination immunotherapy (antibody against TNF- α , J5 antiserum against endotoxin, and a *Pseudomonas* O-serotype-specific opsonophagocytic monoclonal antibody) was greater than the one afforded by any combination of two antibodies or single antibody therapy (Gross *et al.*, 1993).

What, then, is the clinical experience with inhibitors of the activity of NOS? Early reports of beneficial hemodynamic effects of L-NMMA in humans with septic shock (Petros *et al.*, 1994) stimulated a phase I, multicenter, open-label, dose-escalation (1, 2.5, 5, 10, or 20 mg/kg/hour for up to 8 hours) study using L-NMMA (546C88) in 32 patients with septic shock. In this study, L-NMMA sustained blood pressure and enabled a reduction in vasopressor (norepinephrine) support. The cardiac index fell (possibly due to an increase in peripheral vascular resistance), and left ventricular function was well maintained. Moreover, L-NMMA increased oxygen extraction, while pulmonary shunt was not worsened (Watson *et al.*, 1995). This first study was followed by a placebo-controlled multicenter study involving 312 patients with septic shock, which evaluated the effects of L-NMMA on the resolution of shock at 72 hours (primary endpoint) (Grover *et al.*, 1999). The severity of illness according to the SAPS II score was similar between placebo and the L-NMMA group. Infusion of L-NMMA enhanced mean arterial blood pressure and systemic vascular resistance index and decreased cardiac output (from elevated toward normal levels). L-NMMA had no effect on left ventricular systolic work index, indicating that the fall in cardiac output was not due to an impairment in cardiac contractility. In patients treated with L-NMMA, there was a transient increase in mean pulmonary artery pressure. Interestingly, L-NMMA did not affect the thrombocytopenia or renal dysfunction caused by sepsis. Most notably, 41% of patients treated with L-NMMA,

but only 21% of patients treated with placebo, recovered from shock within 72 hours. There was a strong trend for a reduction in mortality (at day 14) in patients treated with L-NMMA.

In June 1997, Glaxo Wellcome started a phase III clinical trial evaluating the effect of 546C88 (targinine, L-NMMA) in patients with septic shock. The trial was stopped by the company in spring 1998, because of concerns about a higher mortality in the treated group than in the placebo group at an interim analysis. The trial, which involved 177 centers from 26 countries, started in June 1997. It had enrolled 797 patients at the time of suspension. The interim analysis included data from 522 patients, 309 of whom had received 546C88. The data and safety monitoring committee reported a trend toward increased mortality in the active treatment group and thus recommended stopping the trial because of patients' safety concerns. The trial will not be resumed, and it is unlikely that development of the drug will continue (SCRIP, 1998; No. 2330, p. 21).

The reasons for the discrepancy in outcome between animal experiments (with agents that prevent the induction or the activity of NOS) and clinical trials are not entirely clear, but they may include (i) relatively late intervention in clinical trials (compared to pretreatment in animal studies), (ii) inhomogeneity of patients (e.g., differences in age, gender, causes of shock, severity of disease), or (iii) the pharmacology (dose regimen, time of intervention, length of treatment) of the intervention chosen. In addition, it is possible, if not likely, that inhibitors of NOS activity, such as L-NMMA, that are not selective for iNOS may exert side effects arising from excessive vasoconstriction. Clearly, the pathophysiology leading to the circulatory failure, organ dysfunction, and ultimately death in patients with septic shock is multifactorial.

Concluding Remarks

More than a decade has passed since the discovery that an enhanced formation of NO contributes to the circulatory failure in patients with septic shock. Although the effects of selective inhibitors of iNOS activity have not been evaluated in controlled clinical trials, there is good evidence that an enhanced formation of NO by iNOS contributes to the circulatory failure associated with septic shock in humans. A therapy-refractory fall in blood pressure (in the absence of MODS) is—only in some cases—the underlying cause of mortality of patients with septic shock. Thus, it appears likely that interventions aimed at eliminating the detrimental effects of a single mediator (“single-bullet approach to the therapy of shock”), although useful in some acute animal models, are less likely (if not unlikely) to cause a significant reduction in 28-day mortality in patients with septic shock.

Nitric Oxide and Vascular Disease

John P. Cooke, Randy Mont-Reynaud, Philip S. Tsao, and Andrew J. Maxwell

*Section of Vascular Medicine
Stanford University School of Medicine
Stanford, California*

NITRIC OXIDE (NO) IS A POTENT REGULATOR OF VESSEL TONE, STRUCTURE, AND INTERACTION WITH CIRCULATING BLOOD ELEMENTS. IN HEALTHY INDIVIDUALS, THE VASODILATION INDUCED BY NO ENHANCES BLOOD FLOW BY INCREASING VASCULAR COMPLIANCE AND REDUCING VASCULAR RESISTANCE. NO INHIBITS THE PROLIFERATION OF VASCULAR SMOOTH MUSCLE CELLS AND PREVENTS ADHERENCE OF PLATELETS AND LEUKOCYTES TO THE VESSEL WALL. NO ALSO PLAYS AN IMPORTANT ROLE IN ANGIOGENESIS. IN INDIVIDUALS WITH RISK FACTORS FOR ATHEROSCLEROSIS (E.G., HYPERTENSION, HYPERCHOLESTEROLEMIA, DIABETES MELLITUS, TOBACCO EXPOSURE, AND AGING) NO ACTIVITY AND/OR SYNTHESIS ARE IMPAIRED. THE IMPAIRMENT IS MULTIFACTORIAL AND DEPENDENT UPON ASSOCIATED CONDITIONS AND THE STAGE OF VASCULAR DISEASE, BUT THE END RESULT IS PATHOPHYSIOLOGICAL INCREASES IN VASCULAR RESISTANCE AND CHANGES IN VASCULAR STRUCTURE THAT RESULT IN ATHEROSCLEROSIS, MEDIAL HYPERTROPHY, MYOINTIMAL HYPERPLASIA, AND/OR THROMBUS FORMATION, AS WELL AS IMPAIRED ANGIOGENIC RESPONSE TO OCCLUSIVE ARTERIAL DISEASE. ONE OF THE DERANGEMENTS OF THE NO SYNTHASE PATHWAY THAT CONTRIBUTES TO THESE PATHOPHYSIOLOGIES IS COMPETITIVE INHIBITION OF NO SYNTHESIS BY THE ENDOGENOUS ANTAGONIST ASYMMETRIC DIMETHYLARGININE. NEW INSIGHTS INTO THE MECHANISMS OF THIS DERANGEMENT MAY LEAD TO A NEW THERAPEUTIC AVENUE IN THE TREATMENT OF VASCULAR DISEASE.

Introduction

The endothelium is a delicate and diaphanous film of tissue that lines all blood vessels. Despite its apparent fragility, this tissue exerts significant influence over vessel tone, structure, and interaction with circulating blood elements. The endothelium elaborates a remarkable panoply of paracrine products to serve these functions and to preserve a balance between vasoconstriction and vasodilation, between cell proliferation and quiescence, and between coagulation and blood fluidity. Generally, within the healthy vessel wall the endothelial factors that predominate are those that induce vasodilation, prevent coagulation, and suppress cell adherence and growth. However, under certain conditions, the balance may be shifted. For example, the endothelium syn-

thesizes tissue plasminogen activator, thrombomodulin, and heparans that favor fluidity of the blood. However, the endothelium also is capable of producing von Willebrand factor, plasminogen activator inhibitor, and adhesive glycoproteins that participate in coagulation and cell adherence. This diversity of endothelial synthetic function maintains blood flow but provides the physiological flexibility for the endothelium to respond to conditions that demand hemostasis.

The same delicate balance exists for the endothelial regulation of vascular growth. Ordinarily the endothelium suppresses the proliferation of the underlying vascular smooth muscle cells by its elaboration of nitric oxide (NO), prostacyclin, and transforming growth factor β (TGF- β). However, the endothelium is also capable of producing agents

that stimulate vascular growth, including platelet-derived growth factor, basic fibroblast growth factor (bFGF), and insulin-like growth factor.

Finally, the endothelium regulates vascular tone. By its production of nitric oxide, prostacyclin, endothelium-derived hyperpolarizing factor, natriuretic peptide, and adrenomedullin, the endothelium maintains the systemic circulation in a vasodilated state, although it is also capable of producing vasoconstrictors such as endothelin and angiotensin II.

In the healthy vessel, the endothelial factors that predominate are those that favor vasodilation, blood fluidity, and cell quiescence. Endothelium-derived nitric oxide is paradigmatic of an endothelial factor that induces vasodilation, and which opposes inflammation, thrombosis, and cellular proliferation. Disorders that disturb the synthesis or activity of nitric oxide result in vasculopathies characterized by vasoconstriction, inflammation, thrombosis, and/or initiation of the cell cycle. Hypercholesterolemia, hypertension, hyperglycemia, hyperhomocysteinemia, tobacco exposure, and aging each cause endothelial dysfunction that contributes to the vascular disease associated with these conditions. The endotheliopathy that precedes and contributes to vascular disease is multifactorial, and it is dependent on the underlying metabolic disorder. Insights have been obtained regarding the mechanisms of these endotheliopathies which may lead to new therapeutic strategies.

Derangement of the NO Synthase Pathway in Atherosclerosis

In animal models of atherosclerosis, and in human patients, endothelium-mediated NO-dependent vasodilation is impaired (Bossaller *et al.*, 1987; Celermajer *et al.*, 1992; Ludmer *et al.*, 1986; Verbeuren *et al.*, 1986). The impairment in endothelium-dependent vasodilation occurs early in the course of disease, and it affects the peripheral and myocardial conduit and resistance vessels of animals and humans exposed to risk factors for atherosclerosis (Cohen *et al.*, 1988; Creager *et al.*, 1990; Zeiher *et al.*, 1991). The loss of normal endothelium-dependent vasodilation results in abnormal vasomotion. This has clinical consequences. For example, the normal coronary vasodilation to an increase in blood flow is reversed to a vasoconstriction in individuals with coronary artery disease, which undoubtedly contributes to exercise-induced angina (Nabel *et al.*, 1990). Furthermore, in hypercholesterolemic individuals with coronary artery disease, aggressive antilipid therapy improves coronary endothelial function and reduces myocardial ischemia, as documented by Holter monitoring of ST segment changes (Treasure *et al.*, 1995; Andrews *et al.*, 1997).

The impairment of endothelium-dependent vasodilation is multifactorial and dependent on the vessel and species studied, the stage of atherosclerosis, and the associated metabolic disorders (Förstermann *et al.*, 1989; Tesfamariam *et al.*, 1992; Ohara *et al.*, 1993; Kikuta *et al.*, 1998; Lerman *et al.*, 1995; Girerd *et al.*, 1990; Pritchard *et al.*, 1995; Cosentino and Katusic, 1995; Stroes *et al.*, 1995; Vallance *et al.*, 1992).

The mechanism of impairment may include endothelial generation of superoxide anion (O_2^-) and increased degradation of NO, elaboration of vasoconstrictor prostanoids and endothelin, reduced elaboration of prostacyclin, and/or impaired biosynthesis of NO (Förstermann *et al.*, 1989; Tesfamariam *et al.*, 1992; Ohara *et al.*, 1993; Lerman *et al.*, 1995; Girerd *et al.*, 1990). Impaired biosynthesis of NO may be due to (1) alterations in NOS affinity for L-arginine, (2) lipid-induced impairment of the high-affinity cationic amino acid transporter (CAT), (3) reduced availability of the cofactor tetrahydrobiopterin, or (4) increased levels of asymmetric dimethylarginine (ADMA), the competitive inhibitor of nitric oxide synthase (NOS) (Vallance *et al.*, 1992; Cosentino and Katusic, 1995; Stroes *et al.*, 1995; Pritchard *et al.*, 1995; Kikuta *et al.*, 1998). Our group and others have accumulated extensive data to indicate that ADMA is a major determinant of endothelial vasodilator dysfunction in humans at risk for atherosclerosis.

We and others have shown that endothelial vasodilator dysfunction in hypercholesterolemic animals or humans could be reversed by administration of L-arginine (Cooke *et al.*, 1991a; Creager *et al.*, 1992; Drexler *et al.*, 1991). We found that in hypercholesterolemic humans, the impaired forearm blood flow response to the endothelial agonist methacholine is rapidly normalized by intravenous infusion of L-arginine but not D-arginine (Creager *et al.*, 1992). Similarly, in patients with atherosclerotic or transplant coronary artery disease, the impairment of acetylcholine-induced vasodilation of the epicardial and coronary resistance vessels is reversed by an intravenous infusion of L-arginine (Drexler *et al.*, 1991, 1994).

Our initial reports regarding the reversibility by L-arginine of endothelial vasodilator dysfunction were met with some skepticism. By the time our work was published, Förstermann and colleagues had characterized the kinetics of NOS and found that, *in vitro*, the K_m of NOS for L-arginine was in a micromolar range (Pollock *et al.*, 1991). Because human plasma L-arginine levels are 50–100 μM , L-arginine should not be rate limiting. However, our studies were confirmed and extended by a number of other investigators. In animal models or in patients with hypercholesterolemia and/or atherosclerosis, the studies are remarkably concordant (Bode-Böger *et al.*, 1996a; Maxwell *et al.*, 1998; Böger *et al.*, 1995; Clarkson *et al.*, 1996; Davies *et al.*, 1995; Drexler *et al.*, 1991; Dubois-Randé *et al.*, 1992; Goode and Heagerty, 1995; Hutchison *et al.*, 1997; Mehta *et al.*, 1996; Randall *et al.*, 1994; Rossitch *et al.*, 1991; Schushke *et al.*, 1994). There are several explanations for the “arginine paradox,” including the following: effects of hypercholesterolemia and/or atherosclerosis on NOS affinity (Pritchard *et al.*, 1995), the effect of glutamine to inhibit activation of NOS (Arnal *et al.*, 1995), a reduction in the availability of the cofactor tetrahydrobiopterin (Cosentino and Katusic, 1995), the colocalization to the caveolar membrane of NOS and CAT (the

cationic amino acid transporter that mediates L-arginine influx) (McDonald *et al.*, 1997), and reduced arginine transport due to lipid-induced impairment of the high-affinity CAT (Kikuta *et al.*, 1998) or to elevation in plasma levels of ADMA (asymmetric dimethylarginine). Localization of NOS and CAT to the caveolar membrane may explain the sensitivity of the NOS pathway to reductions in extracellular L-arginine levels (Hutchison *et al.*, 1997).

ADMA is a competitive inhibitor of NOS. ADMA is derived from the methylation of internal arginine residues in proteins; hydrolysis of these proteins produces ADMA (note that ADMA is not produced by methylation of free arginine, and the plasma ADMA level is not affected by L-arginine intake) (Bode-Böger *et al.*, 1996b). ADMA is excreted by the kidney or metabolized by DDAH (dimethylarginine dimethylaminohydrolase) to citrulline and dimethylamine (MacAllister *et al.*, 1996). Normal plasma levels are 0.5 to 1 μM (Vallance *et al.*, 1992). Intriguingly, plasma levels of ADMA are elevated in a number of conditions associated with endothelial vasodilator dysfunction including renal failure, hypercholesterolemia, hyperhomocysteinemia, hypertension, diabetes mellitus, and heart failure (Vallance *et al.*, 1992; Usui *et al.*, 1998; Matsuoka *et al.*, 1997; Böger *et al.*, 1998a). In patients with renal failure, ADMA levels are increased 10-fold (Vallance *et al.*, 1992). Plasma from renal failure patients induces vasoconstriction of vascular rings, which is reversible by addition of L-arginine to the medium (Vallance *et al.*, 1992). Dialysis normalizes plasma ADMA levels and improves endothelium-dependent relaxation of peripheral vessels in these individuals (Hand *et al.*, 1998).

Luscher and colleagues have previously shown that flow-mediated vasodilation (FMVD) of the brachial artery is largely mediated by endothelium-derived NO (Joannides *et al.*, 1995). Flow-mediated vasodilation is impaired in individuals with atherosclerosis or risk factors for atherosclerosis. The degree of impairment is related to the number of cardiovascular risk factors present, among which the plasma low density lipoprotein (LDL) cholesterol level may be one of the most important (Celermajer *et al.*, 1994). The mechanism(s) leading to this defect may include an increased degradation and/or reduced synthesis of NO (Minor *et al.*, 1990; Cooke and Dzau, 1997a). In young asymptomatic hypercholesterolemic subjects, we have shown that plasma ADMA levels are doubled in association with an arginine-reversible impairment of FMVD of the brachial artery (Figs. 1 and 2). Intriguingly, the impairment of FMVD is better correlated to the arginine/ADMA ratio than it is to LDL cholesterol levels (Böger *et al.*, 1997a).

We measured plasma levels of L-arginine and ADMA by high-performance liquid chromatography (HPLC) in 49 hypercholesterolemic and 31 normocholesterolemic individuals (Böger *et al.*, 1998b). ADMA levels were elevated twofold in hypercholesterolemic individuals (2.2 ± 0.2 versus 1.0 ± 0.1 $\mu\text{mol/liter}$), whereas L-arginine levels were similar. In a segment of the entire study group, measurements of flow-mediated vasodilation of the brachial artery were made using duplex ultrasonography. Flow-mediated

Figure 1 Plasma ADMA in hypercholesterolemic (H) and normal (N) subjects (modified from Böger *et al.*, 1998b, *Circulation* 98(18), 1842–1847). *Values are slightly different.

vasodilation and urinary nitrate excretion, which are indicators of endothelium-derived NO activity or biosynthesis, were inversely correlated to plasma ADMA levels. This study suggests that elevated plasma ADMA levels in hypercholesterolemia impair NO biosynthesis in humans.

The two- to threefold elevation of plasma ADMA that is observed in patients with hypercholesterolemia and/or atherosclerosis is physiologically significant. Faraci *et al.* (1995) found that concentrations of ADMA at these levels inhibit endothelium-dependent relaxation of basilar arteries in the hamster. Added to crude purified preparations of endothelial NOS (eNOS), ADMA in a physiological or pathophysiological range (1 to 10 μM) induces a dose-dependent inhibition of NO synthesis. Accordingly, at the concentrations observed in hypercholesterolemic patients, ADMA inhibits NO biosynthesis. Furthermore, when the arginine/ADMA ratios are mimicked in *in vitro* experiments, cultured endothelial cells increase their production of superoxide anions and reduce the activity of NO.

Figure 2 L-Arginine infusion restores endothelium-dependent vasodilation in hypercholesterolemic (HC) subjects (modified from Böger *et al.*, 1998b, *Circulation* 98(18), 1842–1847). NC, normal control. *Values are slightly different; n.s., not significantly different.

Figure 3 Vascular NO synthesis is increased by L-arginine (modified from Tsao *et al.*, 1994).

The doubling of ADMA plasma concentrations in hypercholesterolemic (HC) subjects may reflect an even greater level of this endogenous NO synthase inhibitor within endothelial cells. In experimental models of vascular injury, there is attenuated endothelium-dependent vasodilation even after the intimal lining has been fully regenerated (Weidinger *et al.*, 1990). It has been shown that in regenerated endothelial cells, levels of ADMA (as well as another NO synthase inhibitor, L-monomethylarginine) are elevated threefold compared with normal cells (Azumi *et al.*, 1995).

In hypercholesterolemic New Zealand White (NZW) rabbits, plasma ADMA levels are elevated twofold (Böger *et al.*, 1995; Yu *et al.*, 1994). In these animals, endothelium-dependent NO-mediated vasodilation of the aorta and resistance vessels is impaired. We have directly measured the vascular synthesis of NO by the rabbit thoracic aorta. Animals were fed a high cholesterol diet for 2 weeks and were given L-arginine (2.5%) or vehicle in the drinking water *ad libitum*, which resulted in a doubling of plasma arginine levels. The production of nitrogen oxides by the thoracic aortas (as measured by chemiluminescence) was increased in animals receiving supplemental L-arginine (Fig. 3) (Tsao *et al.*, 1994). This study demonstrates directly that administration of L-arginine enhances vascular NO synthesis.

The endothelial dysfunction induced by hypercholesterolemia has adverse effects at the level of the resistance vessels. As mentioned earlier, prior to the development of obstructive disease in the conduit vessels, hypercholesterolemia impairs the agonist-induced increases in coronary and limb blood flow in hypercholesterolemic animals and humans (Osborne *et al.*, 1989). This impairment of microvascular response has physiological consequences. For example, we have observed that exercise tolerance is reduced in hypercholesterolemic Apo E-deficient mice, in part due to an impairment of exercise-induced increases in limb blood flow (Maxwell *et al.*, 1998). When mice are exercised on a treadmill in a metabolic chamber, the maximal oxygen uptake and the distance run by Apo E-deficient (E^{-} animals) mice are less than controls. This abnormality appears to be due in large part to a reduced ability to deliver blood to the

Figure 4 Basal (open bars) and peak exercise (solid bars) distribution of cardiac output to gastrocnemius and quadriceps muscles expressed as percentage of total cardiac output in E^{+} , E^{+} L-NA, and E^{-} mice (Maxwell *et al.*, 1998, *Circulation* 98(4), 369–374).

exercising limbs (Fig. 4). Mice were placed on a treadmill, and fluorescent microspheres were injected (through a cannula inserted from the left carotid artery into the thoracic aorta) at rest or during maximal exercise. Limb blood flow during exercise was reduced in E^{-} animals. Furthermore, the expected increase in urinary nitrogen oxide (U_{NOx}) after exercise was absent in E^{-} animals (Fig. 5). ADMA levels are increased in E^{-} animals, and vascular NO biosynthesis is reduced (as measured in aortic segments by chemiluminescence). Administration of L-arginine (6% solution *ad libitum*) for 1 week prior to exercise enhanced distance run during exercise (by 61%) and elevated U_{NOx} postexercise by fivefold in E^{-} mice. In contrast, administration of the NOS inhibitor L-nitroarginine (L-NA) to normal mice reduced limb blood flow and distance run during exercise.

To summarize, NO plays a critical role in exercise-induced increases in limb blood flow. These findings are consistent with those of Böger *et al.* (1997a, 1998c) in patients with peripheral arterial disease whereby L-arginine enhances NO biosynthesis (Fig. 6) and limb blood flow.

Figure 5 Exercise-induced increase in NO biosynthesis is abrogated in E^{-} mice (modified from Maxwell *et al.*, 1998, *Circulation* 98(4), 369–374).

Figure 6 L-Arginine infusion increases urinary nitrate in patients with peripheral arterial disease (modified from Böger *et al.*, 1998c).

In patients with peripheral arterial disease, plasma ADMA levels are elevated two- to fivefold and are correlated to the clinical severity of the disease (Boger *et al.*, 1997a). In patients with critical limb ischemia due to atherosclerosis, an intravenous infusion of L-arginine (30 g over 30 min) increases limb blood flow (approximately twofold) and to the same extent as prostaglandin E_1 (PGE_1) (Maxwell *et al.*, 1998). This is significant because PGE_1 is demonstrably effective in relieving rest pain and healing ischemic ulcers in these individuals (European Working Group on Critical Leg Ischemia, 1991). The observed increase in limb blood flow in these patients is due to the conversion of the exogenous L-arginine to NO, as reflected by parallel increases in urinary nitrogen oxides (Fig. 6) and urinary cGMP (Böger *et al.*, 1997a).

These effects of L-arginine are associated with symptomatic relief in patients with peripheral arterial disease. In a randomized placebo controlled trial, intravenous administration of L-arginine (8 g twice daily) for 2 weeks, improved walking distance by 150%, significantly better than vehicle and the active control PGE_1 (Böger *et al.*, 1998c).

Symptomatic benefits of L-arginine are also observed in individuals with coronary artery disease (CAD) (Lerman *et al.*, 1998; Ceremuzynski *et al.*, 1997). Investigators at the Mayo Clinic reported a double-blind placebo controlled trial of L-arginine (9 g per day) in patients with symptomatic CAD (Lerman *et al.*, 1998). The coronary blood flow response to intracoronary acetylcholine (10^{-6} M) was markedly depressed at the start of therapy but was dramatically improved after 6 months of therapy with L-arginine (an absolute increase of 149% compared to 6% for placebo). Angina episodes were reduced by 70% in the L-arginine-treated group after 1 week, an effect that was maintained at 6 months. A similar response to oral L-arginine was observed by Ceremuzynski *et al.* (1997). They observed that in comparison to placebo, treadmill-walking time is significantly increased, as is time to 1 mm ST segment depression in CAD

patients given L-arginine capsules orally (6 g p.o. daily) (Lerman *et al.*, 1998).

These data indicate that there is an impairment of the NOS pathway in atherosclerosis that is at least in part mediated by ADMA. Endothelial vasodilator dysfunction is reversed by intravenous or oral administration of L-arginine, which appears to be due to its conversion to nitric oxide. The subsequent improvements in coronary or peripheral blood flow provide symptomatic relief. Therefore, it appears that the elevation in plasma ADMA is of physiological relevance. Accordingly, an understanding of the mechanisms by which ADMA becomes elevated is of scientific merit and potential clinical relevance.

Dysregulation of DDAH: Novel Mechanism for Endothelial Dysfunction

As previously mentioned, plasma ADMA is elevated in patients with renal failure due to reduced clearance. In these individuals, dialysis clears ADMA from the plasma and improves endothelium-dependent vasodilation, as does administration of L-arginine (Hand *et al.*, 1998).

Plasma ADMA is elevated in patients with atherosclerosis, as well as in patients with risk factors for atherosclerosis, such as hypercholesterolemia, hypertension, diabetes mellitus, tobacco exposure, and hyperhomocysteinemia. However, in these individuals the elevation in plasma ADMA levels is likely not due to reduced renal clearance. We have developed evidence that reduced degradation of ADMA may be involved in the observed increase in plasma ADMA levels in hypercholesterolemia and hyperglycemia.

Dimethylarginine dimethylaminohydrolase (DDAH) is the enzyme that degrades ADMA to citrulline and dimethylamine (MacAllister *et al.*, 1996). We have accumulated data indicating that a reduction in DDAH activity may be responsible for the elevation in ADMA observed in conditions where glucose and/or cholesterol are elevated. Specifically we have observed that when cultured endothelial cells are exposed to oxidized LDL cholesterol (ox-LDL, 0–100 μ g/ml) or tumor necrosis factor α (TNF- α) (0–200 IU), they elaborate increased amounts of ADMA into the conditioned medium (Fig. 7). During this time there was no change in the expression of DDAH mRNA or protein by Northern or Western analysis, respectively. However, the increase in ADMA accumulation is temporally related to a decline in the activity of the DDAH enzyme (Fig. 8). These data indicate that the increase in ADMA observed in hypercholesterolemia may be due to a decline in its degradation by DDAH (Ito *et al.*, 1999a). In subsequent studies, we extended this observation *in vivo*, demonstrating that DDAH activity is depressed by 50% in the thoracic aorta of NZW hypercholesterolemic rabbits (Ito *et al.*, 1999a).

To summarize, DDAH activity of endothelial cells was decreased to almost 60% of the baseline values by incubation with oxidized LDL or tumor necrosis factor. Similarly,

Figure 7 ADMA release by human aortic endothelial cells (HAECs) is increased by oxidized lipoprotein or cytokine stimulation (modified from Ito *et al.*, 1999a, *Circulation* 99, 3092–3095).

DDAH activity was significantly decreased in rabbits fed a high cholesterol diet, in the absence of any changes in the protein expression. These results are similar to those obtained when endothelial cells are exposed to *S*-2-amino-4-(3-methylguanidino)butanoic acid (4124W) (1 mM), which inhibits DDAH activity and increases the accumulation of ADMA in the conditioned medium of endothelial cells (MacAllister *et al.*, 1996).

Intriguingly, we observed similar results when endothelial cells are exposed to high glucose conditions. Accordingly, we examined another model of endothelial vasodilator dysfunction, the streptozotocin-treated rat. In these animals, hyperglycemia induced by streptozotocin was associated with an increase in plasma ADMA levels and a decline in DDAH activity in the vessel wall without a change in DDAH expression by Western analysis (Ito *et al.*, 1999b). These studies indicate that the increase in plasma ADMA observed in hypercholesterolemia or hyperglycemia may be due to reductions in DDAH activity. ADMA and DDAH are widely distributed in tissues (Kimoto *et al.*, 1995), and they may provide a mechanism for controlling NO synthesis in physiological and/or pathological states. Our results reveal that

Figure 8 DDAH activity is reduced by oxidized lipoprotein or cytokine stimulation (modified from Ito *et al.*, 1999a, *Circulation* 99, 3092–3095).

lipoproteins or cytokines may increase endothelial elaboration of ADMA by reducing DDAH activity. Decreased activity of DDAH may lead to local accumulation/release of intracellular ADMA and inhibition of NO synthase in disease states including hypercholesterolemia. The increase in ADMA levels may explain the therapeutic benefit of supplemental L-arginine observed in patients with endothelial dysfunction (Lerman *et al.*, 1998).

The mechanism for the depression of DDAH activity has not been delineated. However, DDAH has critical sulfhydryl groups in its structure, and SH-blocking agents such as *p*-chloromercuribenzoate and HgCl₂ are known to inhibit enzyme activity (Ogawa *et al.*, 1987). It may be that oxidative stress induced by hypercholesterolemia or hyperglycemia reduces DDAH activity by oxidizing these critical sulfhydryl groups.

Hypertension and NOS

Nitric oxide plays a major role in the regulation of systemic vascular resistance. It is therefore conceivable that endothelial vasodilator dysfunction could precipitate hypertension. Indeed, an endothelial abnormality is associated with hypertension in animal models (Lüscher *et al.*, 1987). Depending on the experimental model, the reduction in endothelium-dependent relaxation is due to an attenuation of endothelium mediated NO-dependent activity or is due to the augmented elaboration of an endothelium-derived contracting factor (possibly a prostanoid). Whether endothelial dysfunction is primary in the initiation of hypertension or is merely an epiphenomenon is not clear. Treatment of the elevated blood pressure normalizes endothelium-dependent relaxation, suggesting that the endothelial abnormality is secondary in the hypertensive process (Cooke and Dzau, 1997a,b; Lüscher *et al.*, 1987; Shultz and Rajj, 1989). Conversely, infusions of nitric oxide synthase antagonists produce marked increases in blood pressure in experimental animals (Ribeiro *et al.*, 1992). These inhibitors have been considered nonspecific, and the effect on blood pressure could conceivably be due to an effect on the neuronal NOS. However, more definitive data for a primary role of nitric oxide in the regulation of blood pressure was provided by Huang *et al.* (1995). They found that inactivation of the mouse endothelial nitric oxide synthase gene by homologous recombination produced mice that were significantly hypertensive.

There is extensive evidence for endothelial vasodilator dysfunction in hypertensive humans (Linder *et al.*, 1990; Panza *et al.*, 1990). The most direct evidence has come from measurements of forearm blood flow by strain-gauge plethysmography in response to intra-arterial infusions of endothelium-dependent and -independent vasodilators. In young patients with mild essential hypertension, endothelium-independent vasodilation is relatively undisturbed. In contrast, cholinergic vasodilation (presumably endothelium-dependent) is attenuated. Whether this is a primary or secondary phenomenon is not known. The impairment of en-

dothelium-dependent vasodilation is likely multifactorial and may involve abnormalities of signal transduction, NO activity, or NO biosynthesis. There is preliminary evidence that, at least in some cases, the endothelial deficit may precede the appearance of essential hypertension (Panza *et al.*, 1990). In young normotensive individuals with hypertensive parents cholinergic forearm vasodilation is impaired; in contrast, endothelium-independent vasodilation is normal.

NO and Angiogenesis

In addition to the role of NO as a potent vasodilator, data from our laboratory and others suggest that NO plays a critical role in angiogenesis. First, a number of angiogenic factors are known to stimulate the NOS pathway. Vascular endothelial growth factor (VEGF) stimulates the release of NO from cultured human umbilical venous endothelial cells (HUVECs), as well as upregulates the expression of NOS (Hood *et al.*, 1998; Van der Zee *et al.*, 1997). Vascular segments of rabbit thoracic aorta release NO in response to VEGF; preincubation with L-arginine increases basal and VEGF-stimulated NO release twofold (Murohara *et al.*, 1998a). Transforming growth factor β (TGF- β) upregulates eNOS in bovine aortic endothelial cells (BAECs) and increases NO elaboration as detected by chemiluminescence (Inoue *et al.*, 1995). In the rat, acidic or basic fibroblast growth factor (bFGF) dilates skeletal muscle microvessels and increases blood flow, an effect that is blocked by NOS inhibitors but not by indomethacin (Wu *et al.*, 1996). Similarly, bFGF relaxes porcine coronary arterioles by an NO-dependent mechanism (Tiefenbacher and Chilian, 1997). VEGF-induced vascular permeability is also mediated in part by NO (Murohara *et al.*, 1998a). Second, the angiogenic effect of a number of growth factors is mediated in part by nitric oxide. Human umbilical venous endothelial cells grown in a three-dimensional fibrin matrix form a network of capillary-like tubules under the influence of bFGF or VEGF or TGF- β . The effect of bFGF, VEGF, or TGF- β to induce endothelial tubule formation is abrogated by inhibitors of NOS (Babaei *et al.*, 1998; Papapetropoulos *et al.*, 1997a,b). Furthermore, administration of NO donor agents mimics this effect of angiogenic factors *in vitro* (Babaei *et al.*, 1998; Papapetropoulos *et al.*, 1997b).

The healing of acid-induced ulcerations of the rat stomach is dependent on angiogenesis. Administration of FGF enhances healing, an effect which is associated with increased expression of eNOS; the effect of FGF is blocked by NOS antagonists (Akiba *et al.*, 1997). Administration of L-arginine, but not D-arginine, enhances gastric blood flow and healing of ulcers, effects that are abrogated by antagonists of NOS (Brzozowski *et al.*, 1995, 1997).

Significantly, in conditions associated with reduced NO bioactivity, angiogenesis is attenuated. Vascular explants from rabbit thoracic aorta or human coronary artery will manifest capillary-like outgrowth when placed into a collagen matrix (Chen *et al.*, 1997; Chen and Henry, 1997). The growth of these capillary-like microtubes is inhibited by ox-

idized LDL cholesterol (Chen *et al.*, 1997; Chen and Henry, 1997), which is also known to reduce NO bioactivity (Kugiyama *et al.*, 1990; Simon *et al.*, 1990). In hypercholesterolemic rabbits, endothelium-dependent nitric oxide-mediated vasodilation is blunted, as is the angiogenic response to hind limb ischemia (Van Belle *et al.*, 1997). More definitively, the angiogenic response to hind limb ischemia is impaired in the eNOS-deficient mice, an effect that cannot be reversed by VEGF (Murohara *et al.*, 1998a).

The mechanisms by which NO mediates angiogenesis are incompletely understood. However, under certain experimental conditions NO enhances endothelial cell proliferation and migration (Morbidelli *et al.*, 1996; Ziche *et al.*, 1994, 1997). NO may enhance migration by increasing endothelial cell podokinesis (Noiri *et al.*, 1998) and/or by increasing the expression of the endothelial integrin $\alpha_v\beta_3$, which is involved in endothelial migration (J. Isner, 1999, personal communication). NO may also increase the production of urokinase-type plasminogen activator (uPA) via its upregulation of bFGF (Ziche *et al.*, 1997). The NO-induced activation of uPA is significant, since migration of endothelial cells requires dissolution of the surrounding extracellular matrix. Finally, the hemodynamic effects of this potent vasodilator may play a role in its angiogenic effects. Increased shear stress (induced by administration of prazosin) in the skeletal microcirculation is associated with increased uptake of bromodeoxyuridine by capillary endothelial cells; this indicates that endothelial cell proliferation may be stimulated by increases in blood flow (Hudlicka, 1998).

ADMA: An Endogenous Antiangiogenic Factor

Studies indicate that endothelium-derived nitric oxide plays a critical role in angiogenesis (see earlier). Accordingly, we hypothesized that ADMA, by inhibiting NOS, may be an endogenous antiangiogenic factor. We have used a disk-angiogenesis system (DAS) to test this hypothesis (Kowalski *et al.*, 1992). The disk is composed of a polyvinyl alcohol sponge covered on both surfaces by filter paper so that vessel ingrowth occurs only from the side. A slow-release pellet containing a pro or anti growth factor can be placed in the center of the disk. The disk is implanted subcutaneously and harvested 2 weeks later. The disk is sectioned and stained, and the surface area of fibrovascular growth (which is directly related to the area of vascular ingrowth) is measured. Figure 9 shows a high-power photomicrograph of the disk revealing endothelium-lined tubes. These capillary-like structures are in continuity with the systemic circulation as indicated by intraluminal leuconyl blue which was injected into the aorta prior to sacrifice (Fig. 9).

In hypercholesterolemic Apo E-deficient mice (E^{-}), plasma ADMA levels are elevated, and aortic NO synthesis is reduced (Maxwell *et al.*, 1998). In these animals, basal and FGF-stimulated angiogenesis in the disk is attenuated in comparison to normal animals (E^{+}). Dietary administration of L-arginine normalizes angiogenesis in the hypercholester-

Figure 9 High power photomicrograph of fibrovascular growth into alcohol sponge placed subcutaneously. Note the capillaries outlined by leuconyl blue dye injected systemically prior to sacrifice.

olemic E^- animals (Fig. 10). In contrast, oral administration of the NOS inhibitor L-nitroarginine (L-NA) inhibits angiogenesis in normal (E^+) animals. These studies indicate that NO biosynthesis is required for normal angiogenic response.

More recently, we have examined the role of ADMA in modulating angiogenesis in a murine model of hind limb ischemia. After the surgical induction of hind limb ischemia, normocholesterolemic mice exhibit a 70% reduction in exercise tolerance. Over a period of 7 weeks, the animals recover to their baseline treadmill performance. In association with this recovery, there is an increase in capillary density and an associated improvement in hind limb blood flow as measured by magnetic resonance (MR) perfusion studies. In comparison, the recovery from hind limb ischemia of hypercholesterolemic Apo E-deficient mice is blunted, as assessed by the histological and MR parameters. Oral administration of L-arginine to the animals in their drinking water restores the angiogenic response. In contrast, administration of L-nitroarginine to the normal animals impairs angiogenic response as assessed by the histological and functional measures.

NO and Atherogenesis

In addition to its effects on vascular reactivity and angiogenesis, NO inhibits platelet aggregation, leukocyte adhesion, proliferation of vascular smooth muscle, and endothelial generation of superoxide anion, all of which are key processes in atherogenesis (Bath *et al.*, 1991a,b; Clancy *et al.*, 1992; Garg *et al.*, 1989; Kubes *et al.*, 1991; Niu *et al.*, 1994; Radomski *et al.*, 1987; Stamler *et al.*, 1989). NO exerts its effects on these processes acutely through cGMP-mediated phosphorylation of signaling proteins, but also via cGMP-independent effects on transcriptional events. NO suppresses the transcription of oxidant-sensitive genes, including adhesion molecules mediating monocyte infiltration. NO may exert this effect by (1) combining directly with superoxide anion to form peroxynitrite anion; (2) inhibiting oxidative enzymes and/or terminating the autocatalytic chain of lipid

Figure 10 Angiogenesis in subcutaneously implanted disks is inhibited by hypercholesterolemia (Ho *et al.*, 1999). E^- stands for Apo E-deficient hypercholesterolemic mice; E^+ , normal mice; L-Arg, L-arginine added to the drinking water; L-NA, nitroarginine added to the drinking water.

peroxidation, and/or (3) enhancing the expression of mRNA for I κ B α , the protein inhibitor of NF- κ B (Garg *et al.*, 1989; Hogg *et al.*, 1993; Niu *et al.*, 1994; Spiecker *et al.*, 1997). The antiatherogenic effects of NO may be due in part to its inhibition of oxidative stress.

The interaction of nitric oxide and superoxide anion forms the highly reactive free radical peroxynitrite anion, which is generally deemed to enhance oxidative stress. However, it is possible that peroxynitrite anion could subsequently nitrosate sulfhydryl groups to form S-nitrosothiols. This class of molecules is known to induce vasodilation, inhibit platelet aggregation, and interfere with leukocyte adherence to the vessel wall (Radomski *et al.*, 1987; Stamler *et al.*, 1992).

Another mechanism by which NO may ameliorate oxidative stress is by terminating the autocatalytic chain of lipid peroxidation that is initiated by ox-LDL or intracellular generation of oxygen-derived free radicals. Indeed, exogenous NO inhibits copper-induced oxidation of LDL cholesterol, causing a lag in the formation of conjugated dienes (Hogg *et al.*, 1993). Alternatively, NO may directly suppress the generation of oxygen-derived free radicals by nitrosylating, and thereby inactivating, oxidative enzymes. This hypothesis is supported by the observation that the generation of superoxide anion by stimulated neutrophils is reduced by their exposure to exogenous NO (Niu *et al.*, 1994). This is due to the inactivation of NADPH oxidase, a multimeric enzyme with cytosolic and particulate components. The particulate component is vulnerable to nitrosylation by NO (at either its heme moiety or sulfhydryl group), which prevents its association with the cytosolic component and reconstitution of the active enzyme. A similar phenomenon may occur in endothelial cells. This would explain the observation of Niu and colleagues (1994), who reported that antagonism of endogenous NO production increases oxidative stress in HUVECs, as demonstrated with redox-sensitive fluorophores. Furthermore, Pagano and colleagues (1993) showed that exogenous NO donor agents inhibit the generation of

superoxide anion by the endothelium of rabbit thoracic aortas treated *ex vivo* with antagonists of superoxide dismutase.

It is well established that hypercholesterolemia reduces the activity and/or synthesis of endothelium-derived NO (Heistad *et al.*, 1984; McLenahan *et al.*, 1991). In parallel, the endothelium begins to generate superoxide anion (Ohara *et al.*, 1993). It is currently believed that the resulting endothelial oxidative stress triggers a transcriptional cascade that results in the activation of genes encoding molecules that regulate endothelial adhesiveness (Marui *et al.*, 1993; Weber *et al.*, 1994). Cytokines and lysophosphatidylcholine induce the expression by HUVECs of vascular cell adhesion molecule-1 (VCAM-1), an endothelial immunoglobulin implicated in monocyte adhesion and atherogenesis (Cybulsky and Gimbrone, 1991; DeCaterina *et al.*, 1995). This expression is regulated by an NF- κ B-mediated transcriptional pathway that is blocked by exposure of the cells to the antioxidant pyrrolidinedithiocarbamate or aspirin (Marui *et al.*, 1993; Weber *et al.*, 1994).

The cytokine-induced activation of vascular cell adhesion molecule-1 and macrophage colony-stimulating factor in human saphenous vein endothelial cells is suppressed by NO donor agents (DeCaterina *et al.*, 1995; Peng *et al.*, 1995). This effect of NO appears to be due in part to stabilization and/or increased expression of I κ B α , which complexes with NF- κ B to inhibit its transcriptional activity (DeCaterina *et al.*, 1995).

Zeiher and colleagues (1995) observed that NO inhibits monocyte chemotactic protein 1 (MCP-1) expression in cytokine-stimulated HUVECs in a cGMP-independent fashion. Our data are also consistent with this model of an oxidant-responsive NF- κ B-mediated pathway that is modulated by NO.

Because ADMA inhibits eNOS, it is capable of activating the oxidant-sensitive transcriptional pathways that result in endothelium-monocyte interaction. To demonstrate this, we exposed endothelial cells to ADMA or to the synthetic NOS inhibitor L-NMMA (both 0.1–100 μ M), each of which induced a concentration-dependent inhibition of NO formation that was reversed by coincubation with L-arginine (1 mM). The biologically inactive stereoisomer symmetric dimethyl-arginine (SDMA) did not inhibit NO release. ADMA or L-NMMA (10 μ M) increased endothelial superoxide elaboration (by 110 and 150%, respectively; $p < 0.05$). A similar elevation of superoxide release was induced by 100 mg/dl of native LDL (nLDL) (+140%). ADMA and L-NMMA also stimulated MCP-1 formation by endothelial cells. This effect was paralleled by activation of the redox-sensitive transcription factor NF- κ B. Preincubation of endothelial cells with ADMA or L-NMMA increased the adhesiveness of endothelial cells for THP-1 human monocytoïd cells in a concentration-dependent manner. ADMA- and L-NMMA-induced monocyte binding was diminished by L-arginine or by a neutralizing anti-MCP-1 antibody. These studies indicated that ADMA, the endogenous NO synthase antagonist, induces an endothelial oxidative stress that activates oxidant-responsive genes involved in monocyte adhesion.

Figure 11 Northern analysis of aortic mRNA (Tsao *et al.*, 1997). Expression of monocyte chemotactic protein (MCP-1) in the rabbit thoracic aorta is increased by feeding the animals a 1% cholesterol diet (CHOL) for 2 weeks, an effect that is partially reversed by the coadministration of L-arginine (CHOL + ARG). Normocholesterolemic animals administered the NOS antagonist L-nitroarginine (L-NA) manifest a marked increase in aortic MCP-1 expression. LPS represents a positive control, namely, an aortic segment from normal animal treated *ex vivo* for 2 hours with bacterial lipopolysaccharide.

NO also regulates oxidant-sensitive gene expression *in vivo* (Fig. 11). We find that in hypercholesterolemic animals, chronic administration of supplemental L-arginine doubles plasma arginine levels and causes a sustained increase in vascular NO generation, as measured *ex vivo* by chemiluminescence (Tsao *et al.*, 1997). In contrast, administration of L-NA suppresses vascular NO generation. Vascular generation of superoxide anion is increased by 2 weeks of a high cholesterol diet, and it is reversed by coadministration of supplemental L-arginine. Hypercholesterolemia increases MCP-1 expression in the thoracic aorta of the NZW rabbit, an effect that is attenuated by administration of L-arginine (Fig. 11) (Tsao *et al.*, 1997). In contrast, inhibition of NO generation by the NOS antagonist L-NA in the rabbits markedly increases vascular expression of MCP-1. Using an *ex vivo* functional binding assay, we demonstrated that hypercholesterolemia increased endothelial adhesiveness for monocytes (Tsao *et al.*, 1994). Administration of L-arginine to the hypercholesterolemic rabbits reduced endothelial adhesiveness, whereas administration of the NOS inhibitor L-NA markedly increased endothelial adhesiveness for monocytes.

Chronic dietary manipulation of NO synthesis affects the progression of lesion formation in hypercholesterolemic animals. Administration of L-arginine to fat-fed NZW rabbits for 10 weeks restores endothelial vasodilator function and markedly inhibits progression of intimal lesions (Fig. 12) (Cooke *et al.*, 1992; Wang *et al.*, 1994). Inhibitory effects of L-arginine on atherogenesis have been confirmed by other investigators in the fat-fed NZW rabbit as well as in the LDL receptor knockout mouse (Aji *et al.*, 1997; Candipan *et al.*, 1996; Cayatte *et al.*, 1994; Davies *et al.*, 1995). In contrast, chronic administration of NOS inhibitors increases endothelium-monocyte interaction and accelerates lesion formation in the fat-fed NZW rabbit (Cayatte *et al.*, 1994; Tsao *et al.*, 1995).

Figure 12 Oral administration of L-arginine decreases plaque area in the hypercholesterolemic rabbit (Cooke *et al.*, 1992). *, Significantly different from CHOL value.

The antiatherogenic effect of L-arginine is at least as potent as 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase) inhibition in animal models (Böger *et al.*, 1997b). Böger and colleagues (1997b) fed NZW rabbits a 1.0% cholesterol diet for 16 weeks, together with vehicle, lovastatin, or supplemental L-arginine. Lovastatin reduced total cholesterol levels and inhibited lesion formation in the carotid artery by 55%. L-Arginine had no effect on the lipoprotein profile, but it enhanced endothelium-dependent, NO-mediated vasodilation, reduced vascular generation of O_2^- , and inhibited lesion formation by 68%.

Flow, NO, and Vascular Disease

The distribution of atherosclerotic lesions throughout the vascular tree is nonuniform. As early as the nineteenth century, the great pathologists Rokitsansky (1952) and Virchow (1860) independently speculated that this nonuniformity was due to local alterations in hemodynamic forces impinging on the vascular tree. Indeed, at sites vulnerable to plaque formation, namely, bends, branches, and bifurcations, unidirectional laminar flow is disturbed, with areas of recirculation characterized by low and fluctuating shear stress (Asakura and Karino, 1990; Cornhill *et al.*, 1985; Glagov *et al.*, 1988; Montenegro and Eggen, 1968; Sinzinger *et al.*, 1980). In these regions of low shear stress, the vulnerability to plaque formation may be a result of enhanced monocyte binding. Adhesive interactions between leukocytes in the vessel wall are less likely to be disrupted under conditions of low shear stress. Furthermore, experimental reductions of blood flow enhance endothelial adhesiveness for monocytes (Walpolo *et al.*, 1993, 1995). This may be in part because low-shear regions exhibit enhanced permeability to macromolecules, including LDL. Accumulation and modification of LDL in the vessel wall could trigger a cascade of events leading to changes in the chemotactic and adhesive properties of the

endothelium (Berliner *et al.*, 1995; Schwenke and Carew, 1988; Walpolo *et al.*, 1995).

Tractive forces of fluid flow also modulate the gene expression of endothelial adhesion molecules and cytokines that participate in monocyte binding. In the NZW rabbit, an adhesion molecule homologous to the human vascular adhesion molecule-1 (VCAM-1) is upregulated by hypercholesterolemia and is expressed at sites of early lesion formation (Cybulsky and Gimbrone, 1991; Li *et al.*, 1993). The expression of VCAM-1 in a murine endothelial cell line is reduced by 75% after 24 hours of exposure to laminar fluid flow (Ohtsuka *et al.*, 1993). The expression of VCAM-1 is regulated in part by oxidant-responsive transcriptional activation (Marui *et al.*, 1993). Oxidized LDL and cytokines induce the expression of VCAM-1 via a transcriptional pathway modulated by NF- κ B; this NF- κ B-mediated gene expression can be abrogated by antioxidants (Marui *et al.*, 1993).

The most important physiological stimulus of endothelial NO synthesis is blood flow (Cooke *et al.*, 1990, 1991b; Pohl *et al.*, 1986). We and others have demonstrated that the tractive force of fluid flow stimulates the release of endothelium-derived NO and increases the expression of NO synthase. In addition to its major role in flow-mediated vasodilation, the release of NO under conditions of flow may influence circulating blood elements.

Flow-stimulated NO has acute effects on monocyte-endothelial cell interaction, as well as more chronic effects on the expression of genes mediating monocyte adherence. Monocyte adherence to endothelial cells in culture may be inhibited by administration of NO with a short time course that implies an effect on signal transduction of adhesion pathways (Bath *et al.*, 1991b). We have also shown that the adherence of monocytoid cells to bovine aortic endothelial cells is inhibited by brief (i.e., 15-min) exposure to NO donor agents or by increases in endogenous NO in the absence of any changes in expression of VCAM-1 or intracellular adhesion molecule-1 (ICAM-1) (Tsao *et al.*, 1995).

However, chronic exposure of endothelial cells to laminar flow may have a chronic and persisting effect on their adhesiveness for monocytes. We have examined the long-term effects of laminar flow on endothelial adhesiveness for monocytes. Confluent monolayers of human aortic endothelial cells were exposed to static or fluid flow conditions for 4 hours. The medium was replaced, and cells were then incubated with native or oxidized LDL or lipopolysaccharide (LPS) plus TNF- α for an additional 4 hours. Functional binding assays using THP-1 monocytes were then performed. Superoxide production by human aortic endothelial cells was monitored by lucigenin chemiluminescence, and expression of VCAM-1 and ICAM-1 were quantified by flow cytometry. Whereas native LDL had little effect, incubation with either oxidized LDL or LPS/TNF- α significantly increased superoxide production, NF- κ B activity, VCAM-1 expression, and endothelial adhesiveness for monocytes. Previous exposure to fluid flow inhibited these sequelae of exposure to cytokines or oxidized lipoprotein. The effect of

fluid flow was due in part to shear-induced release of NO, because coincubation with L-NA completely abolished these effects of flow. These studies indicated that the flow-induced release of NO suppressed endothelial generation of superoxide anion and thereby inhibited an oxidant-sensitive transcriptional pathway for endothelial adhesive molecules (Tsao *et al.*, 1996).

These effects of flow were mimicked by the NO donor agent PAPA-NONOate, whereas a cGMP analog had only a partial effect. This implies that NO exerts its effects in part by cGMP-independent pathways. Similarly, Zeiher *et al.* (1995) found that cGMP analogs did not mimic the effect of exogenous NO donor agents in inhibiting NF- κ B activity and MCP-1 expression in cultured endothelial cells. This is in contrast to the *in vivo* work of Kurose and colleagues (1993), who found that the enhanced adhesion of leukocytes to vessels perfused by nitro-L-arginine methyl ester could be completely reversed by 8-Br-cGMP. This discrepancy may be due to other effects of the cGMP analog *in vivo* (e.g., vasodilation with attendant increases in flow or direct effects on monocyte adhesive proteins). However, Kuchan and Frangos (1993) have also demonstrated that the negative regulation of endothelin-1 by flow is dependent on NO and is mimicked by 8-Br-cGMP. The mechanism of action may differ from that in the present study, as the endothelin promoter does not appear to contain an NF- κ B consensus sequence.

It is interesting to note that the effects of fluid flow seen in the study by Tsao *et al.* (1996) persisted even after cessation of flow. In contrast, NO production quickly falls to baseline levels after cessation of fluid flow. Kanai *et al.* (1995) used a porphyrinic microsensor to detect NO elaborated by cultured endothelial cells in response to fluid flow. With cessation of the flow stimulus, the NO concentration in the conditioned medium declined at a rate that would be predicted by oxidative degradation of the NO released into the medium during flow. This observation suggests that NO elaboration ceases instantaneously with discontinuation of the flow stimulus. However, in the study by Tsao *et al.*, the effect of flow on endothelial adhesiveness persisted for at least 4 hours. We speculate that this persistent effect may be due to the inactivation by NO of oxidative enzyme activity, which probably has a long time constant, given the extraordinary affinity of NO for heme proteins.

We found that the effects of flow to inhibit NF- κ B-mediated VCAM-1 expression and endothelial adhesiveness could be accounted for by elaboration of endogenous NO. The effect of NO on NF- κ B and I κ B, however, may not totally explain the effects of flow on VCAM-1 expression or monocyte binding. VCAM-1 promoter activity has been demonstrated to be under the complex control of both stimulatory and inhibitory *trans*-activating factors. Moreover, deletion analysis has demonstrated that NF- κ B binding activity is important for optimal stimulation of the VCAM-1 promoter but is not essential for VCAM-1 transcription. In addition, NF- κ B activity does not fully explain the effect on adhesion molecule expression, since ICAM-1 expression

was only minimally affected by NO. Other nuclear binding proteins may dominate in cytokine- or lipid-induced ICAM-1 expression. Furthermore, the ICAM-1 promoter contains the shear stress responsive element (SSRE) GAGACC first defined by Resnick *et al.* (1993). This SSRE may contribute to the positive regulation by shear stress of ICAM-1 that we have observed. This same SSRE is found in the promoter region of a number of genes regulated by flow, including endothelial cell NOS (Marsden *et al.*, 1993; Nishida *et al.*, 1992). Therefore, mechanisms independent of NO may contribute to the effects of flow on endothelial adhesiveness. For example, flow enhances the release of prostacyclin and increases the expression of superoxide dismutase, which might also contribute to the flow-induced inhibition of endothelial adhesion (Frangos *et al.*, 1985; Inoue *et al.*, 1996; Kubes *et al.*, 1991).

Nevertheless, the acute and chronic effects of NO on endothelial adhesiveness may play an important role in atherogenesis. The effect of habitual exercise in inhibiting atherosclerotic lesion formation (Haskell *et al.*, 1994; Richard *et al.*, 1990) may be due in part to the effect of exercise in enhancing the vascular expression of endothelial cell NOS and elaboration of NO (Sessa *et al.*, 1994). Similarly, the predisposition to lesion formation at sites of branching may be due in part to the reduced elaboration of NO at these sites (McLenahan *et al.*, 1991). This speculation is supported by our previous observations that enhancement of vascular NO activity in the hypercholesterolemic rabbit inhibits endothelial adhesiveness for monocytes and reduces lesion formation (Cooke *et al.*, 1992; Tsao *et al.*, 1994; Wang *et al.*, 1994). In contrast, chronic administration of NOS antagonists enhances endothelial adhesiveness and increases monocyte accumulation in the vessel wall (Cayette *et al.*, 1994; Naruse *et al.*, 1994). Similar effects of NO on endothelial cell-neutrophil interactions have been observed in hypercholesterolemia (Lefer and Ma, 1993). Taken together, these studies implicate NO as an endogenous antiatherogenic molecule, which exerts its effects in part via its modulation of oxidant-responsive transcriptional pathways. Derangements in the NOS pathway, induced by various risk factors, impair the regulation by NO of the oxidant responsive transcriptional pathway, leading to the expression of adhesion molecules and chemokines involved in monocyte adhesion (Fig. 13).

Regression and Progression: Dependency on NO

In 1996 we published our findings that administration of L-arginine to hypercholesterolemic rabbits with preexisting lesions can induce apparent regression of preexisting intimal lesions (Candipan *et al.*, 1996). Specifically, NZW rabbits were fed a 0.5% cholesterol diet for 10 weeks, at which time they exhibited intimal lesions occupying 30% of the surface area of the thoracic aorta. Subsequently, animals received L-arginine (2.25%) or vehicle in their drinking water while the 0.5% cholesterol diet was continued. Thoracic aortas

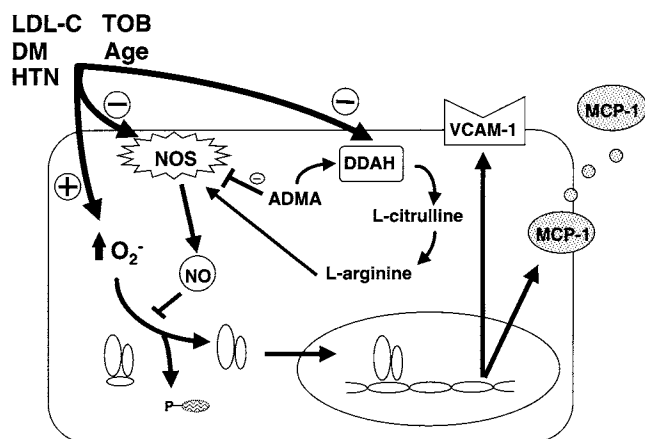

Figure 13 Cardiovascular risk factors may induce atherogenesis, in part, by modulation of the nitric oxide pathway. DM, diabetes mellitus; HTN, hypertension; TOB, tobacco; NOS, NO synthase; ADMA, asymmetric dimethylarginine; DDAH, dimethylarginine dimethylaminohydrolase; VCAM-1, vascular cell adhesion molecule; MCP-1, monocyte chemotactic protein.

were harvested at subsequent weeks for vascular reactivity studies and histomorphometry. In those animals receiving vehicle, there was a progressive impairment of endothelium-dependent vasodilation and an increase in lesion surface area (to 60% of the thoracic aorta) over the course of weeks 10 to 23. In contrast, in the L-arginine-treated group, there was an improvement in endothelium-dependent vasodilation and a significant reduction in lesion surface area. Indeed, after 23 weeks, those L-arginine-treated animals that still manifested an improvement in endothelium-dependent NO-mediated vasodilation exhibited a lesion surface area of only 5% (Candipan *et al.*, 1996).

This study suggested to us that enhancement of vascular NO activity could induce regression of preexisting intimal lesions. We hypothesized that NO-induced regression may be mediated by apoptosis of cells in the intimal lesion. To test this hypothesis, male NZW rabbits were fed a 0.5% cholesterol diet for 10 weeks to develop intimal lesions. After 10 weeks L-arginine hydrochloride (2.5%) was added to the drinking water, and the cholesterol diet was continued for 2 weeks, at which time the aortas were harvested for histological studies. L-Arginine treatment increased the number of apoptotic cells (largely macrophages) in the intimal lesions by threefold. In subsequent studies, aortas were harvested for *ex vivo* studies. Aortic segments were incubated in cell culture medium for 4 to 24 hours with modulators of the NO synthase pathway. The tissues were then collected for histological studies, and the conditioned medium was collected for measurement of nitrogen oxides by chemiluminescence. Addition of sodium nitroprusside (10^{-5} mol/liter) to the medium caused a time-dependent increase in apoptosis of vascular cells (largely macrophages) in the intimal lesion. L-Arginine (10^{-3} mol/liter) had an identical effect on apoptosis, which was associated with an increase in nitrogen oxides released into the medium. These effects were not

mimicked by D-arginine, and they were antagonized by the NO synthase inhibitor L-NA (10^{-4} mol/liter). The effect of L-arginine was not influenced by an antagonist of cGMP-dependent protein kinase, nor was the effect mimicked by the agonist of protein kinase G or 8-Br-cGMP. These studies indicate that supplemental L-arginine induces apoptosis of macrophages in intimal lesions by its metabolism to NO, which acts through a cGMP-independent pathway (Wang *et al.*, 1999).

Apoptosis occurs in vascular cells of human atherosclerotic plaques (Bennet *et al.*, 1995; Björkerud and Björkerud, 1996; Geng and Libby, 1995; Han *et al.*, 1995; Isner *et al.*, 1995; Kockx *et al.*, 1996). Factors involved in the initiation and regulation of apoptosis in atherosclerosis have not been fully elucidated, but immunohistochemical studies provide evidence for several proteins known to participate in apoptosis, including p53 and interleukin-1 β -converting enzyme (Isner *et al.*, 1995; Messmer *et al.*, 1994; Messmer and Brune, 1995). Among the myriad pathways that may be involved, there is accumulating evidence to implicate L-arginine/NOS. Cytokine-mediated activation of inducible NOS (iNOS) induces apoptosis of macrophages and vascular smooth muscle cells *in vitro* (Geng *et al.*, 1996a,b; Albina *et al.*, 1993). The effect of iNOS activation *in vitro* is augmented by additional L-arginine and attenuated by antagonists of NOS. In our study, L-arginine-enhanced apoptosis was associated with increases in the level of NO_x released into the medium (Wang *et al.*, 1999). The involvement of the NOS pathway was also indicated by the observation that the effect of L-arginine was blocked by an antagonist of NOS.

Although the evidence in this study supports a role for NO in apoptosis of macrophages, it should be acknowledged that NO has been shown to have antiapoptotic effects as well. NO donor agents have been demonstrated to inhibit apoptosis of cultured endothelial cells and lymphocytes (Dimmeler *et al.*, 1997; Mannick *et al.*, 1994). The effect of NO as a modulator of apoptosis appears to be cell specific and contextual (e.g., dependent on the presence of certain cytokines, growth factors, or oxidative stress) (Geng and Libby, 1995).

It is likely that iNOS expressed by cells within the lesion is responsible for the effect of L-arginine to induce apoptosis of lesion cells and regression. Indeed, previous immunohistochemical studies have detected iNOS in the intimal macrophages and vascular smooth muscle cells of human atherosclerotic plaques (Buttery *et al.*, 1996). Under these conditions, vascular cells also produce superoxide anion (Mügge *et al.*, 1991; Ohara *et al.*, 1993; White *et al.*, 1994). In this milieu, the product of iNOS is quickly transformed into peroxynitrite anion, a highly reactive free radical (Beckman and Koppenol, 1996). Peroxynitrite anion is cytotoxic and may induce apoptosis initially by causing DNA strand fragmentation (Nguyen *et al.*, 1992). Peroxynitrite anion can also affect cell function by nitrosating tyrosine residues that are involved in the signal transduction of transmembrane receptors (Martin *et al.*, 1990). Using monoclonal antibodies directed against nitrotyrosine, evidence of peroxynitrite formation has been observed in human atherosclerotic plaques

(Beckman *et al.*, 1994; Mügge *et al.*, 1991). This is relevant to the observation of L-arginine-induced regression, because peroxynitrite anion may be the NO species mediating macrophage apoptosis.

Previous studies have suggested that apoptosis of macrophages induced by iNOS activity is independent of cGMP (Messmer *et al.*, 1995). Consistent with this observation is our finding that the various manipulations of the cGMP pathway did not influence apoptosis in the lesions of this animal model. In contrast, in cultured vascular smooth muscle cells, NO donor agents induce apoptosis by a cGMP-dependent mechanism (Pollman *et al.*, 1996).

The activation of iNOS may have complex effects on the evolution of atherosclerotic plaques. By inducing cell death, iNOS activation may contribute to the development of the "necrotic core" of complex lesions. One might also speculate that iNOS may be involved in the characteristic atrophy of the media beneath atheroma or the dissolution of the fibrous cap by activated macrophages. NO or peroxynitrite anion produced by activated macrophages could induce apoptosis of vascular smooth muscle (Dimmeler *et al.*, 1997; Rajagopalan *et al.*, 1996). Furthermore, NO or peroxynitrite anion may reduce collagen formation by vascular cells and activate metalloproteinases, which degrade extracellular matrix (Kolpakov *et al.*, 1995; Rajagopalan *et al.*, 1996).

These actions of peroxynitrite anion would contribute to plaque instability and have led some investigators to explore antagonism of iNOS as a potential therapeutic avenue in atherosclerosis. However, it is likely that such a strategy would have unintended consequences. Antagonism of iNOS activity could promote platelet aggregation, leukocyte adherence, vasoconstriction, and proliferation of vascular smooth muscle cells and macrophages. It should be considered that iNOS may be in fact a countervailing force in the accretion of atherosclerotic plaque. Furthermore, by reducing proliferation and by promoting apoptosis of macrophages in the lesion, iNOS activation may lead to plaque stabilization and even regression, as suggested by our observations. It is worthy of emphasis that both macrophages and vascular smooth muscle cells contribute to the intimal lesion in the balloon-injured hypercholesterolemic rabbit, but in our observations of this animal model, apoptosis was largely observed in the central, macrophage-rich area of the lesions. Further evidence to support a role for iNOS as a beneficial force in atherogenesis comes from studies of the iNOS-deficient mouse. In these animals, transplant atherosclerosis is accelerated, indicating that NO derived from iNOS (as well as that derived from eNOS) has beneficial effects on the progression of atherosclerosis, possibly by curtailing inflammation and/or cell proliferation.

Restenosis and NOS

The long-term benefit of coronary balloon angioplasty and atherectomy is limited by the considerably high occurrence of restenosis (40 to 50%) 3 to 6 months after the pro-

cedure (Holmes *et al.*, 1984). Restenosis is in part due to myointimal hyperplasia, a process characterized by vascular smooth muscle cell migration and proliferation (Forrester *et al.*, 1991; Popma *et al.*, 1991). A decrease in total vessel area termed "negative remodeling" or shrinkage also contributes to the luminal encroachment (Kakuta *et al.*, 1994; Post *et al.*, 1994). Medical therapies to prevent smooth muscle cell proliferation have been uniformly unsuccessful, whereas vascular stenting to obtain optimal lumen gain and inhibition of remodeling has modestly reduced the restenosis rate (Fischman *et al.*, 1994; Serruys *et al.*, 1994, 1996). However, intimal thickening still plays a significant role in stent restenosis.

The architecture of the vessel wall is remodeled in response to changes in the balance of paracrine factors that regulate the proliferation and biosynthetic activity of vascular cells. One of the substances that participates in this vascular homeostasis is NO. In addition to relaxing smooth muscle cells, NO inhibits their proliferation (Bath *et al.*, 1991b). As mentioned previously, NO also inhibits the interaction of circulating blood elements with the vessel wall (Bath *et al.*, 1991a,b; Kubes *et al.*, 1991; Radomski *et al.*, 1987; Stamler *et al.*, 1989; Tsao and Lefer, 1990). These effects of vascular NO may explain the observation that long-term administration of L-arginine inhibits myointimal hyperplasia after balloon injury (McNamara *et al.*, 1993; Hamon *et al.*, 1994). Because the endothelium is removed at the time of the intervention and is not fully regenerated at the site of injury for several weeks in this animal model, it is not likely that endothelium-derived NO is responsible for the effect of intramural L-arginine on myointimal hyperplasia. It is more likely that the activity of inducible NO synthase expressed by vascular smooth muscle cells after injury is inhibiting their proliferation. We have directly tested the hypothesis that generation of NO by vascular smooth muscle cells *in vivo* can inhibit their migration and/or proliferation. After balloon-catheter injury, transfection of vascular smooth muscle cells with a plasmid construct containing NO synthase (but not the control vector) enhanced NO generation locally and inhibited myointimal hyperplasia (Von der Leyen *et al.*, 1995).

More recently, in a hypercholesterolemic rabbit model of balloon angioplasty, we have observed that a single intramural administration of a concentrated solution of L-arginine could affect vascular function and structure after balloon angioplasty of the iliac artery. Specifically, administration of L-arginine (800 mg/5 ml over 15 min) with the use of a drug-delivery catheter after angioplasty enhanced vascular NO generation (by fivefold as long as 1 week after the angioplasty), and it inhibited lesion formation by about 60% 4 weeks after the procedure (Schwarzacher *et al.*, 1997). This study is consistent with earlier observations that oral administration of L-arginine suppresses myointimal hyperplasia after vascular injury (McNamara *et al.*, 1993; Tarry and Makhoul, 1994).

After vascular injury and denudation of the endothelium, adjacent endothelial cells begin to proliferate and migrate

into the area of injury. The endothelial cells that resurface the denuded area initially appear morphologically distinct from endothelial cells in noninjured segments of the vessel. The regenerating endothelial cells are cuboidal rather than flat, and they are not aligned with flow. They are also functionally abnormal. Endothelium-dependent NO-mediated vasorelaxation is reduced after vascular injury (Creager *et al.*, 1990; Shimokawa *et al.*, 1987; Verbeuren *et al.*, 1986; Weidinger *et al.*, 1990). The impairment of endothelium-dependent vasodilation is associated with increased intracellular levels of ADMA (Azumi *et al.*, 1995).

ADMA: A Novel Risk Factor for Atherosclerosis?

These preclinical studies pose an intriguing question: Does the reduced activity or elaboration of vascular nitric oxide participate in the progression of atherosclerosis or restenosis in humans? It is quite possible that with a loss of vascular NO activity the processes of inflammation, adhesion, and proliferation would be favored to cause progression of vascular disease and even destabilization of atherosclerotic plaques. Some tantalizing preliminary evidence for this hypothesis is now forthcoming. In patients with coronary artery disease, endothelial vasodilator dysfunction (as assessed by coronary reactivity to acetylcholine) is predictive of vascular events (Murakami *et al.*, 1998). Data from our laboratory are also supportive of this hypothesis. Specifically, in collaboration with Imaizumi and co-workers, we have examined the relationship between plasma ADMA and atherosclerosis in humans (Miyazaki *et al.*, 1999). To identify risk factors in atherosclerosis, subjects ($n = 116$, age 52 ± 1 years, male:female ratio of 100:16) underwent a history and physical examination; determination of serum chemistries and ADMA levels; and duplex scanning of the carotid arteries to quantitate intimal-medial thickness (IMT) (Fig. 14).

Figure 14 ADMA is negatively correlated with flow-mediated vasodilation of the human brachial artery (Böger *et al.*, 1998b).

These individuals had no symptoms of coronary or peripheral artery disease and were taking no medications. Univariate analyses of the effects of each potential risk factor or ADMA on IMT were performed with linear regression for continuous variables (age, systolic, diastolic and mean blood pressure, total cholesterol, response to oral glucose tolerance test [total glucose], and ADMA) and with one-way analysis of variance for categorical variables (smoking and family history). The interaction between risk factors, ADMA, and IMT was then examined using multiple stepwise regression analysis. Multivariate analyses revealed that plasma levels of ADMA were positively correlated to age ($p < 0.0001$), mean arterial pressure, ($p < 0.0001$), and total glucose ($p < 0.0006$) (Fig. 15). Most intriguingly, ADMA levels were better correlated to IMT of the carotid artery ($r = 0.51$, $p < 0.0001$) than to all traditional risk factors including age, arterial blood pressure (systolic, diastolic, or mean arterial pressure), cholesterol (total, LDL, HDL, or triglycerides), plasma glucose (fasting level or AUC after an oral glucose tolerance test), tobacco use, or family history. After stepwise multiple regression analysis, IMT was significantly correlated with age and ADMA only. The correlation between ADMA and IMT was still significant even after adjusting for age ($r = 0.33$, $p = 0.0003$). This study suggests that plasma ADMA may be a novel risk factor for atherosclerosis (Miyazaki *et al.*, 1999). Intriguingly, another study revealed that tissue ADMA is elevated in human atheroma (Matsuoka *et al.*, 1998).

These studies raise the intriguing question of whether enhancement of NO synthesis in humans may have a favorable effect on the progression of vascular disease. Although there is as yet no published evidence that L-arginine therapy prevents progression and/or stabilizes lesions, there is evidence in humans that L-arginine therapy inhibits cellular processes involved in atherogenesis. Specifically, several investigators have shown that L-arginine can inhibit the adhesiveness of peripheral blood mononuclear cells and can inhibit platelet aggregation. The effects on platelet aggregation are modest, but the effect on mononuclear cell adherence is dramatic.

Previous preclinical studies had shown that NO inhibits monocyte and platelet adhesion. Endothelium-derived NO

Figure 15 ADMA is positively correlated with risk factors for carotid atherosclerosis, including age (Miyazaki *et al.*, 1999).

released into the lumen increases platelet cGMP and inhibits platelet aggregation (Kowalski *et al.*, 1992; Pohl and Busse, 1989; Radomski *et al.*, 1987). Accordingly, NO modulates the reactivity of circulating leukocytes and platelets. In hypercholesterolemic (HC) humans, platelet and monocyte adhesiveness is increased. We hypothesized that this might be due in part to a deficit of endothelium-derived NO.

Accordingly, we performed a study to determine the role of ADMA and NOS inhibition in the increased mononuclear cell adhesiveness observed in human hypercholesterolemia. Plasma ADMA levels were determined by HPLC. Functional mononuclear leukocyte adhesion assays were performed in parallel, and flow cytometry was used to characterize bound monocytes and T lymphocytes. Hypercholesterolemic patients were then placed on an oral L-arginine regimen of 14 or 21 g/day and studied over 12 weeks.

Plasma ADMA levels and adhesiveness of mononuclear cells (specifically monocytes and T lymphocytes) were elevated in hypercholesterolemic patients. Adhesiveness was inversely correlated with the plasma L-arginine/ADMA ratio. Oral administration of L-arginine normalized plasma L-arginine/ADMA ratios and attenuated monocyte and T-lymphocyte adhesiveness. These studies revealed that the adhesiveness of circulating monocytes and T cells was augmented by an increase in plasma ADMA level. To determine if this was a direct effect of ADMA on mononuclear cells, or if it was mediated by a suppression of eNOS, we studied the effect of ADMA on isolated monocytes and on those cocultured with endothelial cells. Transformed human umbilical vein (ECV 304) aortic endothelial cells were incubated with varied concentrations of ADMA. Monocytoid cells were cocultured with these cells, and monocytoid cell adhesiveness assessed using a binding assay. Flow cytometry was used to quantitate adhesion molecule expression.

ADMA had no direct effect on the adhesiveness of mononuclear cells. However, monocytes became hyperadhesive when cultured in the conditioned medium from ADMA-exposed endothelial cells.

These studies revealed that in human hypercholesterolemia, the plasma L-arginine/ADMA ratio is inversely correlated with mononuclear cell adhesiveness. Restoration of the L-arginine/ADMA ratio to control levels normalizes mononuclear cell adhesiveness. The elaboration of endothelium-derived NO affects the behavior of circulating T lymphocytes and monocytes, and inhibition of endothelial cell NO production by ADMA leads to hyperadhesive T lymphocytes and monocytes (Chan *et al.*, 2000; Theilmeier *et al.*, 1997).

Monocytes and T lymphocytes are the predominant inflammatory cells found in atherosclerotic plaques. Indeed, the adhesion of mononuclear cells to the endothelium is a key initial event in atherogenesis preceding the formation of fatty streaks (Libby and Hansson, 1991; Ross, 1993; Gimbrone, 1995). In hypercholesterolemic humans, peripheral blood mononuclear cells exhibit increased adhesiveness for endothelial cells in *ex vivo* adhesion assays (Jongkind *et al.*, 1995; Theilmeier *et al.*, 1997). Differences in monocyte sur-

face markers have been detected by flow cytometry between hypercholesterolemic and normocholesterolemic humans, although the functional significance is unclear (Rothe *et al.*, 1996). Molecular signaling mechanisms for the altered behavior of mononuclear cells are likely multifactorial and may involve inflammatory cytokines (Stemme and Hansson, 1994), low density lipoprotein (Berliner *et al.*, 1990; Couffinhal *et al.*, 1993), platelet-activating factor (Lorant *et al.*, 1996), circulating soluble adhesion molecules (Hackman *et al.*, 1996), and reduced bioactivity of endothelium-derived NO.

Nitric oxide has been shown to modulate the behavior of circulating blood elements. *In vivo*, NO inhibits leukocyte adherence in the early stages of hypercholesterolemia in the rat (Gauthier *et al.*, 1995). Furthermore, endothelium-derived NO is able to increase cGMP and reduce the ability of platelets to aggregate as they pass through the microvasculature of the rabbit heart (Pohl and Busse, 1989). In a clinical study of hypercholesterolemic and age- and gender-matched subjects, platelet aggregation to ADP was assessed. Hypercholesterolemic subjects manifested platelet hyperaggregation. In these individuals, administration of L-arginine (8.4 g daily) attenuated platelet aggregation by over 25% (Wolf *et al.*, 1997). Similar effects of treatment with oral L-arginine on platelet and monocyte reactivity (Adams *et al.*, 1995, 1997) have been reported by other investigators. These observations suggest that endothelium-derived NO, released into the lumen, plays an important role as a modulator of leukocyte and platelet function. Changes in the production or bioactivity of endothelium-derived NO can thus be expected to modulate the adhesiveness of circulating blood cells.

Using an independent method, we confirmed observations made by Jongkind *et al.* (1995) that peripheral blood monocytes from hypercholesterolemic patients are hyperadhesive in *ex vivo* adhesion assays (Fig. 16) (Theilmeier *et al.*, 1997). In addition, we found that T (but not B) lymphocytes also exhibit increased adhesiveness in hypercholesterolemia. The increased adhesiveness of circulating

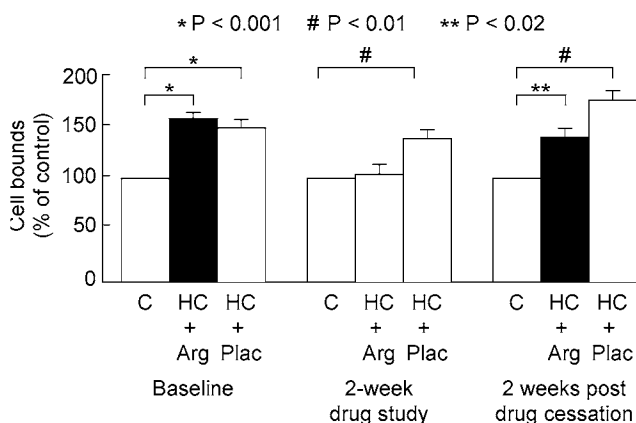

Figure 16 Oral L-arginine reduces mononuclear cell adhesion in hypercholesterolemic individuals (modified from Theilmeier *et al.*, 1997).

monocytes and T lymphocytes in hypercholesterolemic individuals is consistent with the observation that both monocytes and T cells are present in atherosclerotic plaques and adhere to the endothelium in regions predisposed to atherosclerosis before the formation of fatty streaks (Hansson *et al.*, 1991).

Pharmacokinetics, Pharmacoefficacy, and Safety of Oral L-Arginine Administration in Humans

In the reported studies of L-arginine administration and its effects on human vascular biology, no significant adverse effects have been reported. In our own studies, L-arginine supplementation (9 g/day) caused a slight rise in blood urea nitrogen from 14 to 19 $\mu\text{g/dl}$. No other changes in serum chemistries, complete blood count, or lipid profile have been observed. No side effects of L-arginine have been reported by the subjects, except for one case of recurrence of oral herpes lesions, which resolved after discontinuance of L-arginine. However, to gain additional information regarding the clinical administration of L-arginine we have performed pharmacokinetic and pharmacoefficacy studies in different populations.

To learn more about the pharmacokinetics of oral L-arginine, in one study (Tangphao *et al.*, 1999a), eight healthy males (age 43 ± 4 years) with no cardiovascular risk factors were admitted to the General Clinical Research Center at Stanford University in the morning, after an overnight fast, for a 24-hour period of an L-arginine-free diet (diet A) or a diet with a fixed amount of L-arginine intake (3.8 g; diet B), during a 2-day cross-over study. Subjects were randomly selected to begin with diet A or B, and on the second day consumed the other diet. During diet A, plasma L-arginine fell from 21.4 ± 2.0 to 11.9 ± 1.1 $\mu\text{g/ml}$. This study indicated that plasma L-arginine concentrations manifest a diurnal rhythm that is influenced by dietary intake.

A second study was performed to determine if supplemental high-dose L-arginine (14 g/day) was tolerable (Tangphao *et al.*, 1999b), if it would maintain a persistent elevation of plasma L-arginine, and if it would produce a sustained therapeutic effect. We studied 24 hypercholesterolemic (HC) patients (LDL-C 175 ± 5 mg/ml; age 45 ± 3 years) and 18 normocholesterolemic individuals (LDL-C 110 ± 6 mg/ml; age 42 ± 3 years). In HC subjects, basal plasma ADMA levels were elevated by over 60% ($2.1 \pm \mu\text{M}$), whereas plasma L-arginine levels (59 ± 9 μM) were not different. L-Arginine was administered at 14 g/day for 12 weeks to the HC individuals, and plasma L-arginine, ADMA, serum biochemistries, and monocyte studies were performed at 4-week intervals. Oral L-arginine supplementation induced a 60% increase in plasma L-arginine levels, which was sustained throughout the 12-week study. Notably, the plasma ADMA concentration did not change during the study. Furthermore, basal levels of plasma insulin, growth hormone, and glucagon did not increase during L-arginine treatment. There were no significant alterations in serum biochemistries

and hematology studies (except for a clinically insignificant increase in blood urea nitrogen), and no adverse events were reported. Mononuclear cell adhesiveness was increased by 47% in HC individuals and was highly correlated to the ADMA/arginine ratio ($r = 0.62$, $p < 0.0005$). Arginine treatment normalized mononuclear cell adhesiveness, an effect that was maintained for the entire 12-week study period. Together, these studies suggest that high-dose L-arginine is safe in this population of patients, demonstrably increases plasma arginine, and has effects on platelet and monocyte behavior that may be clinically beneficial.

An L-Arginine-Enriched Medical Food for Vascular Disease

As described earlier, there is compelling evidence for the safety and potential benefit of L-arginine in cardiovascular disease. However, the dose of L-arginine required to increase plasma L-arginine levels and to enhance the synthesis of endothelium-derived nitric oxide is in the range of 6–9 g per day. Administered orally in the usual 500 mg tablets, this represents 12–18 capsules daily. The compliance with this many pills would not be high, and in this form, L-arginine therapy is impractical. Another approach would be to increase the intake of dietary L-arginine. The average American diet contains 5.4 g of L-arginine (Visek, 1986). This average intake must be supplemented by 6 to 9 g L-arginine daily to obtain measurable increases in plasma L-arginine and (in hypercholesterolemic individuals) to enhance endothelium-dependent vasodilation and indices of NO biosynthesis (Theilmeier *et al.*, 1997; Böger *et al.*, 1998b). One could increase L-arginine in the diet by selectively using arginine-rich foods. Some foods rich in L-arginine (e.g., red meat) contain saturated fat, which adversely influences endothelial function, and these would not be a good source of L-arginine. Preferably, one should use foods rich in L-arginine (e.g., fish, nuts, legumes, soy protein) that contain other agents that can enhance endothelial function (e.g., eicosapentanoic acid, vitamin E, phytoestrogens) or have other beneficial effects on vascular structure.

A complementary approach is to provide an enriched source of dietary L-arginine. To do so, we developed an L-arginine enriched nutrient bar for the dietary treatment of vascular disease. Because endothelial vasodilator dysfunction is multifactorial and depends on the underlying disorder, it seemed most practical that the bar contain other agents that have been shown to enhance endothelial function. Therefore, in addition to the L-arginine (3.3 g), the bar contains vitamins C (250 mg), E (200 IU), B₆ (2 mg), B₁₂ (5 μg), folate (200 μg), and niacin (25 mg) in a soy protein base.

To determine if this medical food could enhance endothelial vasodilator function, we performed a study in 43 patients with hypercholesterolemia (LDL-C > 160 mg/dl). To assess endothelial function we measured flow-mediated vasodilation of the brachial artery as assessed by high-resolution ultrasound before and after 1 week of treatment with the nutrient bar (two per day) or a placebo control. The placebo

bar contained no vitamins, contained no added L-arginine, and consisted of a whey protein base (whey protein is arginine-poor, with less than 1% arginine residues, whereas soy protein is arginine-rich, at 7% arginine). This study revealed that the L-arginine-enriched bar, but not the placebo bar, normalized flow-mediated vasodilation in middle-aged hypercholesterolemic individuals.

On the basis of these data and the evidence that L-arginine could enhance vascular NO biosynthesis and improve limb blood flow in animal models and in patients with peripheral arterial disease (Bode-Böger *et al.*, 1996a), we studied the effect of the medical food in patients with symptomatic arterial occlusive disease of the extremities. Accordingly, 41 patients with peripheral artery disease underwent treadmill testing (Gardner protocol) and quality-of-life questionnaires (SF-36) before and 2 weeks after treatment with zero, one, or two arginine-enriched nutrient bars daily in a placebo-controlled randomized trial. Patients were studied after an overnight fast (i.e., trough level).

Over the course of 2 weeks of treatment there was no change in lipid profile or serum chemistries, and the bar was well tolerated. Pain-free walking distance improved 66% (over 100 m) in the two bars per day group, and absolute walking distance improved by over 60 m (Fig. 17). Quality of life measures improved significantly in the two bars per day group, but were unchanged in the other two groups. The beneficial effects of the nutrient bar were likely due to the L-arginine content, because a portion of the subjects in the placebo group received a placebo bar containing all the other vitamins of the active bar. However, the soy protein base of the nutrient bar may also have contributed (soy protein has antioxidant effects and phytoestrogenic properties that may influence the vasculature). The effect of the nutrient bar is equivalent or superior to available medical therapy for symptoms of peripheral artery disease. Whereas this small clinical trial is encouraging, it needs to be confirmed by a larger multicenter study.

Contraindications to Therapeutic Use of L-Arginine

Although to date the administration of L-arginine to patients with cardiovascular disease has not been associated with any significant adverse effects, there are theoretical

Figure 17 Increase in total walking distances in patients with claudication after 2 weeks of treatment with an L-arginine-enriched nutrient bar (one or two bars per day) or a placebo bar (Maxwell *et al.*, 2000).

concerns that should be kept in mind when considering the use of L-arginine in certain individuals. Because nitric oxide plays a major role in the hypotension associated with septic shock, the use of L-arginine in patients with a severe infection is not advisable (Kilbourn *et al.*, 1993). Another subset of patients that may be adversely affected by L-arginine administration are those with active autoimmune disorders, where the NOS pathway (and peroxynitrite generation) may contribute to the pathogenesis of these disorders (Nussbaum, 1994; Sakurai *et al.*, 1995; Ueki *et al.*, 1996). Because of the role of NO in angiogenesis, the use of L-arginine may be contraindicated in conditions associated with pathological angiogenesis. Vascular endothelial growth factor may contribute to the pathogenesis of diabetic retinopathy (Aiello *et al.*, 1997). Because the angiogenic effect of VEGF may be in part mediated by NO (Murohawa *et al.*, 1998b), L-arginine should be used with caution in patients with diabetic retinopathy. Finally, the effect of L-arginine in individuals with an active malignancy is unknown. Preclinical studies are mixed, with some demonstrating a beneficial immunomodulatory effect of L-arginine, whereas other studies show an adverse effect of L-arginine on the progression of disease, possibly mediated by an angiogenic effect of L-arginine. In animal models of breast and colon cancer, the majority of studies show beneficial immunomodulatory effects of L-arginine, associated with a reduction in tumor growth and metastasis, and increased survival (Pryme, 1978; Reynolds *et al.*, 1988), although there are some studies that are contradictory (Yeatman *et al.*, 1991). A majority of preclinical and clinical studies indicate a positive immunomodulatory effect of L-arginine administration in other disease states, with increased number and activity of cytotoxic T cells (Barbul *et al.*, 1980, 1981, 1990; Nussbaum, 1994).

L-Arginine (30 g p.o. daily for 3 days) has been given to women with breast cancer. Subsequently, biopsies revealed increased leucine incorporation and PCNA staining in tumor tissue (Park *et al.*, 1992); however, neither tumor growth nor metastasis was examined. Indeed, in a follow-up study of 96 patients with breast cancer, L-arginine (30 g/day for three days) did not increase sensitivity to chemotherapy, an anticipated response if L-arginine stimulated tumor growth (Brittenden *et al.*, 1994a; Heys *et al.*, 1998). Indeed, these investigators found a better histopathological response in the L-arginine treated group, which may be attributed to improved immune function and/or increased tumor cell apoptosis (Brittenden *et al.*, 1994a). In subsequent studies, L-arginine has been shown to have beneficial immunomodulatory effects in women with breast cancer, with an increase in killer T activity (Brittenden *et al.*, 1994b,c; Heys *et al.*, 1998; Park *et al.*, 1992; Pittari *et al.*, 1993). A majority of preclinical and clinical studies indicate a positive immunomodulatory effect of L-arginine administration in other disease states, with increased numbers and activity of cytotoxic T cells (Barbul *et al.*, 1981, 1990; Bode-Böger *et al.*, 1996a; Jongkind *et al.*, 1980).

L-Arginine is widely used as secretagogue in endocrine function studies (30 g i.v.) without adverse effect (Ghigo *et*

al., 1996). L-Arginine is given chronically (21 g p.o. daily for life) to individuals with the inborn error of metabolism resulting in citrullinemia (Visek 1986). L-Arginine has been given (4–8 g p.o. daily) to elderly individuals and to children of short stature in an effort to increase growth hormone levels (so as to increase muscle mass or enhance growth, respectively, in these groups) (Ghigo *et al.*, 1994; Bellone *et al.*, 1993). These doses of L-arginine were well tolerated for up to 6 months in children (Pittari *et al.*, 1993). To summarize, there is extensive experience with the use of L-arginine in a wide variety of cardiovascular and noncardiovascular disorders. In patients with cardiovascular disease, the preponderance of the data indicates that administration of L-arginine enhances endothelial function, particularly in those individuals with atherosclerosis or risk factors for atherosclerosis, particularly those with hypercholesterolemia. Enhancement of endothelial NO synthesis has real clinical benefit, with improvements in limb and coronary blood flow and relief of symptoms in patients with peripheral or coronary artery disease, the rivals more traditional pharmacotherapies. Although the use of L-arginine seems quite safe in most patients, caution should be exercised in those individuals with conditions characterized by pathological angiogenesis or in those patients with severe infectious, inflammatory, or neoplastic disorders, because of the uncertainties with respect to the use of L-arginine in these circumstances.

Conclusion

To conclude, endothelium-derived nitric oxide is a potent modulator of the tone and structure of a blood vessel and of its interactions with circulating blood elements. NO also plays a key role in angiogenesis. Endothelium-derived nitric oxide suppresses many of the key processes involved in atherosclerosis and restenosis, including monocyte adherence, platelet aggregation, vascular smooth muscle proliferation, and generation of oxygen-derived free radicals. NO has acute effects mediated by cGMP as well as more chronic effects on gene expression mediated by its suppression of oxidant-sensitive transcriptional pathways. Accordingly, derangements of the NO synthase pathway lead to vascular disorders characterized by excessive or paradoxical vasoconstriction, inflammation, and cell proliferation. Furthermore, the deficit in NO synthesis or activity may impair the angiogenic response to vascular occlusive disease. Aberrancy of the NO synthase pathway is multifactorial, and it is dependent on underlying disease processes, environmental influences, and the genetic substrate. A greater understanding of the underlying causes of endothelial dysfunction will lead to new therapeutic strategies for atherosclerosis, restenosis, ischemic syndromes, and other vascular disorders.

Cytotoxic Role of Nitric Oxide in Diabetes

Monique R. Heitmeier and John A. Corbett

*Edward A. Doisy Department of Biochemistry and Molecular Biology
Saint Louis University School of Medicine
Saint Louis, Missouri*

INSULIN-DEPENDENT DIABETES MELLITUS IS CHARACTERIZED BY SELECTIVE DESTRUCTION OF INSULIN-SECRETING β CELLS FOUND IN PANCREATIC ISLETS. CYTOKINES, DERIVED FROM ACTIVATED MACROPHAGES AND LYMPHOCYTES, ARE BELIEVED TO PARTICIPATE IN β -CELL DAMAGE BY STIMULATING INDUCIBLE NITRIC OXIDE SYNTHASE (iNOS) EXPRESSION AND NITRIC OXIDE PRODUCTION IN ISLETS. IN ANIMAL MODELS OF AUTOIMMUNE DIABETES, iNOS INHIBITORS HAVE BEEN SHOWN TO ATTENUATE OR DELAY THE ONSET OF DIABETES. IN THIS CHAPTER, THE MECHANISMS BY WHICH CYTOKINES STIMULATE NITRIC OXIDE SYNTHASE EXPRESSION AND THE RAT, MOUSE, AND HUMAN ISLET CELLULAR SOURCES OF THIS ENZYME ARE EXAMINED. ALSO, THE MECHANISMS BY WHICH NITRIC OXIDE IMPAIRS β -CELL FUNCTION AND STIMULATES β -CELL DEATH ARE DISCUSSED. IN ADDITION, STUDIES DEMONSTRATING A ROLE FOR NITRIC OXIDE IN THE DEVELOPMENT OF DIABETES IN ANIMAL MODELS ARE EVALUATED. VIRAL INFECTION HAS BEEN IMPLICATED AS ONE ENVIRONMENTAL AGENT THAT MAY STIMULATE DIABETES IN GENETICALLY SUSCEPTIBLE INDIVIDUALS. IN THIS CHAPTER, EVIDENCE TO SUPPORT A ROLE FOR NITRIC OXIDE IN VIRAL-INDUCED DIABETES IS EXAMINED. LAST, THE ROLE OF NITRIC OXIDE IN MEDIATING β -CELL "BURN-OUT" IN ANIMAL MODELS OF TYPE II OR NON-INSULIN-DEPENDENT DIABETES IS DISCUSSED.

Introduction

Diabetes, defined as an excess of sugar in the blood, is caused by the inability of insulin to stimulate glucose disposal or by the absence or reduced production of insulin by pancreatic β cells. In the United States, 16 million people have been diagnosed with diabetes. This disease is the leading cause of kidney failure, amputations, and blindness, and it is also a major risk factor for cardiovascular disease and stroke (Gaster and Hirsch, 1998; Marre, 1999; Swidan and Montgomery, 1998). In the United States, over \$100 billion is spent annually in health care costs related to diabetes (Pathak and Burke, 1998). This figure is expected to increase, as currently there is no cure for diabetes. Treatments

include agents that either stimulate insulin action or increase insulin production by β cells, and insulin therapy.

There are several types of diabetes. The most common form is type 2 diabetes (non-insulin-dependent diabetes mellitus or NIDDM), a disease that primarily affects adults. Type 2 diabetes was originally termed adult onset because this disease usually occurs in individuals over the age of 40. However, the prevalence of type 2 diabetes is increasing in children, and this increase appears to reflect a similar increase in the number of obese children (Caprio and Tamborlane, 1999; Trissler, 1999). Type 2 diabetes is characterized by defects in insulin secretion by β cells or defects in insulin action. Defects in insulin action usually occur in middle-aged individuals and are associated with obesity (Lebovitz,

1999). In the United States, over 55% of the population is overweight (body mass index over 25 kg/m²), and 80–90% of type 2 diabetics are overweight (Jovanovic and Gondos, 1999; Must *et al.*, 1999).

Type 1 or insulin-dependent diabetes mellitus (IDDM) is the second most common form of diabetes. Type 1 diabetes is caused by an immune-mediated attack directed against insulin-producing β cells found in pancreatic islets of Langerhans (Gepts, 1965). The destruction of β cells results in insulin deficiency that is treated by daily injections of insulin. Type 1 diabetes is typically diagnosed in childhood, but it can occur at any age. Autoimmune destruction of β cells is associated with both genetic risk factors and environmental factors (Bain *et al.*, 1997; Yoon, 1990). The genetic risk factors that most strongly predispose individuals to autoimmune diabetes include the major histocompatibility complex (MHC, or HLA, human leukocyte antigen) found on chromosome 6 (Todd, 1999). Over 80% of type 1 diabetics have an allele in HLA DR3 or DR4; however, many individuals with these alleles do not develop autoimmune diabetes (Todd, 1999). Support for the involvement of environmental factors in the development of autoimmune diabetes comes from the observations that the concordance rate for diabetes in identical twins is less than 40% (Medici *et al.*, 1999; Olmos *et al.*, 1988). Environmental factors that may contribute to autoimmune diabetes include infectious agents, dietary factors, and environmental toxins.

Although it is clear that environmental and genetic risk factors contribute to the development of autoimmune diabetes, the underlining biochemical and immunological mechanisms by which β cells are destroyed are poorly defined. Studies suggest that nitric oxide (NO) may participate in the development of diabetes by functioning as an effector molecule that mediates β -cell damage. In this chapter, evidence to support a role for nitric oxide in mediating β -cell damage during the development of autoimmune diabetes will be reviewed. In addition, the involvement of nitric oxide in mediating β -cell destruction during the development of type II diabetes will also be discussed. Although nitric oxide has been implicated in the regulation of glucose uptake by muscle (Balon, 1998) and in complications of diabetes (Baynes and Thorpe, 1999; Ido *et al.*, 1997), these topics have been covered in other reviews and will not be elaborated in this chapter.

Overview of Autoimmune Diabetes

Autoimmune diabetes is characterized by selective destruction of insulin-secreting β cells found in pancreatic islets of Langerhans (Gepts, 1965). β cells are destroyed during an inflammatory reaction in and around islets, termed insulinitis. A number of inflammatory cell types comprise this destructive insulinitic reaction. These include CD4⁺ and CD8⁺ T lymphocytes, macrophages, and a limited number of β lymphocytes (Bach, 1994). In animal models of diabetes, it has been shown that insulinitis is preceded by peri-insulinitis,

which comprises a mononuclear cellular infiltrate that localizes around the islet periphery (Campbell and Harrison, 1990; Kolb, 1997). T cells are believed to play a primary role in mediating β -cell destruction during the development of autoimmune diabetes. It is possible to transfer diabetes to irradiated nondiabetic animals [both nonobese diabetic mice (NOD) and BioBreeding rats (BB)] using splenocytes obtained from diabetic animals (Like *et al.*, 1985; Wicker *et al.*, 1986), or by transferring purified T cells and T-cell clones established from lesions from diabetic animals (Bergman and Haskins, 1997). Antibody depletion of CD4⁺ and CD8⁺ T lymphocytes prevents the development of diabetes in the NOD mouse, further supporting a role for both subsets of T cells in disease progression (Hayward *et al.*, 1993; Wang *et al.*, 1996). The progression of diabetes is dependent on the T-cell subtype. CD4⁺ Th₁ T cells, which produce interleukin-2 (IL-2) and γ -interferon (IFN- γ), are associated with the progression to diabetes. In contrast, CD4⁺ Th₂ T cells, which produce IL-4 and IL-10, appear to block disease progression (Heurtier and Boitard, 1997; Lafaille, 1998; Rabinovitch, 1998). It is interesting to note that IL-4 and IL-10 have been shown to downregulate cytokine-stimulated inducible nitric oxide synthase (iNOS) expression by macrophages (Erwig *et al.*, 1998; Vouldoukis *et al.*, 1997).

Macrophage participation in disease progression is also essential. Macrophage depletion by silica treatment (Oschilewski *et al.*, 1985; Wright and Lacy, 1989) or by feeding a diet deficient in essential fatty acids (Lefkowitz *et al.*, 1987; Schreiner *et al.*, 1988) prevents the development of autoimmune diabetes in a number of animal models (Benhamou *et al.*, 1995; Lefkowitz *et al.*, 1990; Wright *et al.*, 1988). Macrophages may participate in the development of autoimmune diabetes by (1) producing inflammatory cytokines such as IL-1, IL-6, and tumor necrosis factor (TNF), which may directly damage β cells; (2) producing toxic free radicals (nitrogen and oxygen), which may also mediate β -cell damage; or (3) functioning as antigen presenting cells, thereby stimulating T-cell-dependent destruction of β cells. Figure 1 provides a schematic overview of the potential roles of each of these cell types and inflammatory mediators in the progression of autoimmune diabetes.

Nitric Oxide Mediates Cytokine-Induced Inhibition of Insulin Secretion By β Cells

In vitro studies provided the initial evidence that cytokines modulate β -cell function and mediate islet damage. Mandrup-Poulsen *et al.* (1985) first showed that treatment of isolated rat islets with conditioned medium derived from activated human mononuclear cells results in an inhibition of glucose-stimulated insulin secretion. The active component of this activated culture medium was determined to be the cytokine IL-1 (Bendtzen *et al.*, 1986). IL-1-induced inhibition of insulin secretion is both time and concentration dependent, and it requires mRNA transcription and *de novo*

Figure 1 Schematic diagram of the cellular components of islet inflammation. The development of autoimmune diabetes is characterized by T-lymphocyte, macrophage, and monocyte infiltration into islets. Cytokines produced by these inflammatory cells may participate in the regulation of islet inflammation and may also directly stimulate β -cell expression of iNOS and production of nitric oxide. Nitric oxide produced by β cells and macrophages may directly damage β cells, stimulating the release of autoantigens and further T-lymphocyte-dependent β -cell destruction. In this chapter, evidence supporting a role for inflammatory cytokines (such as IL-1 and IFN- γ) and nitric oxide in mediating β -cell damage during the development of diabetes will be reviewed. See color insert.

protein synthesis (Comens *et al.*, 1987; Hughes *et al.*, 1990; McDaniel *et al.*, 1988; Sandler *et al.*, 1991). The inhibitory effects of IL-1 on insulin secretion are associated with an inhibition in the oxidative metabolism of glucose to CO_2 (Eizirik *et al.*, 1989; Hughes *et al.*, 1990; Sandler *et al.*, 1991). Importantly, insulin secretion by β cells absolutely requires the oxidation of glucose to CO_2 , resulting in the generation of increased levels of ATP within β cells. ATP is required for closure of the ATP-inhibited K^+ channels, leading to β -cell depolarization and Ca^{2+} influx (Misler *et al.*, 1992), events required for glucose-stimulated insulin secretion.

We first hypothesized that nitric oxide may mediate the inhibitory effects of IL-1 on insulin secretion by isolated rat islets (Corbett and McDaniel, 1992). This hypothesis was based on the observations that one of the cellular targets of nitric oxide are enzymes containing iron-sulfur centers, specifically the electron transport chain complexes I and II and the Krebs cycle enzyme aconitase (Drapier and Hibbs, 1996), and that treatment of rat islets with IL-1 results in the inhibition of islet oxidative metabolism (Sandler *et al.*, 1991). In three concurrent studies, we and others showed that treatment of rat islets with IL-1 or IL-1 plus TNF results in the production of nitrite (oxidative metabolite of nitric oxide) and that inhibitors of nitric oxide synthase (NOS) prevent cytokine-induced inhibition of insulin secretion (Corbett *et al.*, 1991; Southern *et al.*, 1990; N. Welsh *et al.*, 1991). Consistent with mitochondrial iron-sulfur centers as targets for nitric oxide-mediated damage, IL-1 was shown to induce the formation of electron paramagnetic resonance (EPR)-detectable iron-nitrosyl complexes by rat islets, to

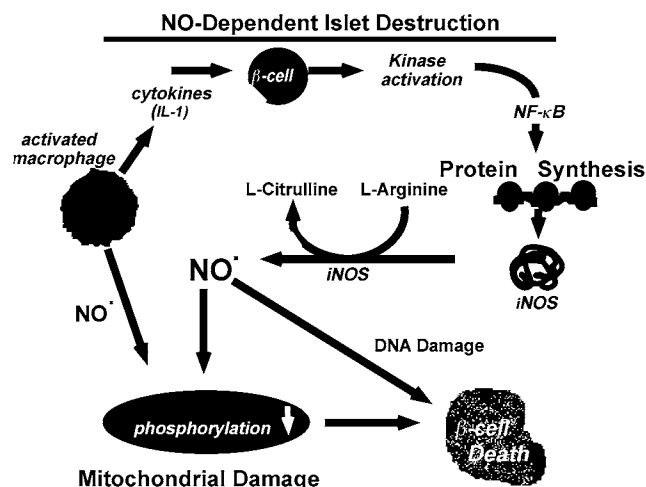

Figure 2 Mechanisms of IL-1-induced β -cell damage. This figure provides a schematic diagram of the mechanisms by which IL-1 stimulates inducible NOS (iNOS) expression and nitric oxide production by β cells, and how nitric oxide mediates β -cell damage. IL-1 binding to surface receptors activates a series of signaling pathways that result in the induction of iNOS mRNA transcription. Nuclear factor κB (NF- κB) appears to play a primary role in the regulation of iNOS expression in response to IL-1; however, other transcriptional activators may also participate. Nitric oxide, produced by β cells, stimulates β -cell damage by inhibiting islet oxidative metabolism and by inducing DNA strand breaks, leading to impairment in glucose-stimulated insulin secretion and β -cell death.

inhibit islet aconitase activity, to inhibit the oxidation of glucose to CO_2 , and to reduce cellular ATP levels in rat islets (Corbett *et al.*, 1995; Cunningham and Green, 1994; Mandrup-Poulsen, 1996). Importantly, the nitric oxide synthase inhibitors N^G -monomethyl-L-arginine (L-NMMA), nitro-L-arginine methylester (L-NAME), and aminoguanidine (AG) prevent all of these effects of IL-1 on islet function (Corbett *et al.*, 1992a, b; Southern *et al.*, 1990; N. Welsh *et al.*, 1991). In addition, studies have shown that islets isolated from iNOS-deficient mice are not adversely affected by *in vitro* treatment with IL-1 or a combination of IL-1 and IFN- γ (Flodstrom *et al.*, 1999). These studies demonstrate that nitric oxide mediates the damaging actions of cytokines on islet secretory function. A working model for the mechanism by which IL-1 inhibits glucose-stimulated insulin secretion by rat islets is shown in Fig. 2.

Does Nitric Oxide Mediate Cytokine-Induced Inhibition of Human Islet Function?

Controversy continues to exist as to whether cytokine-mediated human islet damage is dependent on the production of nitric oxide. Individually, neither IL-1, IFN- γ , nor TNF inhibit glucose-stimulated insulin secretion, nor do they stimulate iNOS expression or nitric oxide production by human islets (Corbett *et al.*, 1993a; Eizirik *et al.*, 1994a). However, in combination, IL-1, TNF, and IFN- γ stimulate iNOS expression, stimulate nitrite production, and inhibit glucose-

stimulated insulin secretion by human islets (Corbett *et al.*, 1993a; Eizirik *et al.*, 1994a). The controversy is directed at whether nitric oxide mediates the inhibitory actions of IL-1 plus TNF plus IFN- γ on human islet function or if cytokine-mediated inhibition of human islet function is independent of nitric oxide production. We first showed that treatment of human islets for 24 hours with IL-1 plus TNF plus IFN- γ results in an $\sim 70\%$ inhibition of insulin secretion that is significantly attenuated by L-NMMA (Corbett *et al.*, 1993a). Eizirik and co-workers showed that a 6-day incubation of human islets with the same combination of cytokines results in an inhibition of insulin secretion that is not prevented by AG, although AG did attenuate cytokine-induced nitric oxide production (Eizirik *et al.*, 1994a). Whereas the findings presented in these two studies appear to be opposed, two important issues may explain the divergent results concerning the role of nitric oxide in mediating cytokine-induced inhibition of insulin secretion by human islets. First, in the Eizirik study, human islets were cultured for 6 days with cytokines (Eizirik *et al.*, 1994a), whereas in our study human islets were cultured for only 24 hours (Corbett *et al.*, 1993a). Second, in the Eizirik study, AG in the absence of cytokines inhibited insulin secretion by human islets to levels similar to the levels inhibited by the combination of cytokines (Eizirik *et al.*, 1994a). In this study, AG was used at a concentration of 5 mM, a level that has been shown to inhibit insulin secretion by rodent islets (Holstad *et al.*, 1997). It is possible that the divergent results obtained in these two studies reflect differences in human islet culture; however, the results in the Eizirik study appear equivocal because AG in the absence of cytokines inhibited insulin secretion to levels similar in magnitude to the inhibitory actions of the cytokine combination (Eizirik *et al.*, 1994a). In support of a role for nitric oxide in the inhibition of insulin secretion, Eizirik and co-workers (Eizirik *et al.*, 1994b) have shown that nitric oxide donor compounds inhibit glucose-stimulated insulin secretion by isolated human islets.

Although the role of nitric oxide in cytokine-induced inhibition of human islet function remains controversial, nitric oxide has been shown to impair human islet oxidative metabolism. We have shown that IL-1 plus TNF plus IFN- γ stimulates the formation of iron-nitrosyl complexes in human islets (Corbett *et al.*, 1993a). In rodent islets, the formation of iron-nitrosyl complexes occurs under conditions in which oxidative metabolism is impaired (Corbett *et al.*, 1991, 1992b). Consistent with an impairment of oxidative metabolism, treatment of human islets with IL-1 plus IFN- γ (minimal combination of cytokines required to stimulate iNOS expression and nitrite formation by human islets) results in an $\sim 60\%$ inhibition of mitochondrial aconitase activity, an effect that is prevented by the iNOS inhibitor AG (Scarim *et al.*, 1997). Since glucose oxidation to CO₂ is required for insulin secretion, and since nitric oxide inhibits human islet aconitase activity (Scarim *et al.*, 1997), we believe that nitric oxide participates in cytokine-mediated human islet damage. Importantly, other factors yet to be identified also appear to participate in cytokine-mediated hu-

man islet damage, as inhibition of iNOS activity does not completely prevent the inhibitory actions of these cytokines on human islet function. This is in contrast to the effects of cytokines on rodent islets, where the inhibition of iNOS activity completely prevents cytokine-induced inhibition of insulin secretion.

Cytokine Requirements for iNOS Expression by Rodent and Human Islets

A wide array of agents (such as cytokines, bacterial and viral products, and proinflammatory molecules) have been shown to stimulate iNOS expression; however, the response to these agents is cell type and species specific (Nathan, 1992). In most cell types, iNOS expression requires a combination of two signals. For example, mouse macrophages require a combination of both TNF and lipopolysaccharide (LPS), LPS and IFN- γ , or IFN- γ and TNF for iNOS induction (Nathan, 1992). In contrast, IL-1 alone is capable of stimulating iNOS expression by rat islets (Corbett *et al.*, 1996; Mandrup-Poulsen, 1996). Similarly to isolated rat islets, insulinoma cell lines such as RINm5F, NIT, HIT, and INS also express iNOS in response to IL-1 (Corbett *et al.*, 1992b; Eizirik *et al.*, 1992; Stephens *et al.*, 1997). Importantly, the individual effects of IL-1 on iNOS expression are potentiated by IFN- γ . IFN- γ reduces the concentration of IL-1 required to stimulate maximal iNOS expression by 10-fold, such that IL-1 at concentrations as low as 0.01 pg/ml (or 0.57 pM) are capable of stimulating iNOS expression by rat islets (Heitmeier *et al.*, 1997). TNF appears to potentiate the level of nitric oxide produced by rat islets by $\sim 10\%$ (Cetkovic-Cvrlje and Eizirik, 1994; Southern *et al.*, 1990); however, TNF does not augment iNOS mRNA accumulation or protein expression, nor does TNF increase the sensitivity of rat islets to IL-1 (M. R. Heitmeier and J. A. Corbett, 2000, unpublished observation).

Islets isolated from most mouse strains require a combination of IL-1 and IFN- γ for iNOS expression (M. Welsh *et al.*, 1995; N. Welsh and Sandler, 1992). IL-1 plus IFN- γ -induced iNOS expression and nitrite formation is increased by $\sim 10\%$ in the presence of TNF (Thomas *et al.*, 1999). Individually, neither IFN- γ nor TNF stimulate iNOS expression by mouse islets (M. R. Heitmeier and J. A. Corbett, unpublished observation). In some mouse strains, IL-1 alone will stimulate iNOS expression by isolated islets; however, for maximal iNOS expression IFN- γ is required in addition to IL-1 (M. Welsh *et al.*, 1995; N. Welsh and Sandler, 1992). Similarly to mouse islets, human islets also require a combination of IL-1 and IFN- γ for iNOS expression (Corbett *et al.*, 1996; Eizirik *et al.*, 1994a). In addition, IL-1 plus IFN- γ -induced iNOS expression by human islets is enhanced slightly by TNF. Alone, neither IL-1, TNF, nor IFN- γ , nor the combinations of IL-1 plus TNF or TNF plus IFN- γ stimulate iNOS expression by human islets (Corbett *et al.*, 1996; Eizirik *et al.*, 1994a).

Table I Expression of iNOS in Islets^a

Islets	Cytokines	Source of iNOS	Functional effects
Rat	IL-1	β cell	Mitochondrial function ↓
	dsRNA + IFN-γ	β cell, macrophage	Secretion ↓
	TNF + LPS	Macrophage, β cell ^b	Islet damage ↓
Human	IL-1 + IFN-γ	β cell	Mitochondrial function ↓
	TNF + LPS + IFN-γ	Macrophage, β cell ^b	Secretion ↓

^aThis table provides a list of agents that stimulate iNOS expression by islets, the cellular source of iNOS, and the effects of iNOS expression on β-cell function.

^bβ-Cell iNOS expression via intra-islet IL-1 release by macrophages.

Proinflammatory agents such as double-stranded RNA (dsRNA) and LPS also stimulate iNOS expression by rat and human islets when incubated in the presence of IFN-γ or TNF. dsRNA (in the form of polyinosinic:polycytidylic acid, polyIC) in combination with IFN-γ stimulates high levels of iNOS expression and nitrite production by both rat (Heitmeier *et al.*, 1999a) and human islets (M. R. Heitmeier and J. A. Corbett, 2000, unpublished observation). The significance of iNOS expression in response to dsRNA will be described in detail in the section concerning mechanisms of viral-induced autoimmune diabetes. Also, the combinations of TNF plus LPS and TNF plus LPS plus IFN-γ stimulate iNOS expression by rat and human islets, respectively (Arnush *et al.*, 1998a; Corbett and McDaniel, 1995). Importantly, iNOS expression in response to TNF plus LPS in rat islets and TNF plus LPS plus IFN-γ in human islets is dependent on the local release of IL-1 in islets following resident macrophage activation. A summary of the agents that stimulate iNOS expression by rat and human islets is shown in Table I.

The Cellular Composition of Islets

Islets are composed of both endocrine and nonendocrine cells (Fig. 3). Insulin-secreting β cells are found in the central core of the islet and comprise ~70% of all islet cells. Glucagon-secreting α cells and somatostatin-secreting δ cells are found on the outer edge of the islet, or the islet mantle. Islets are highly vascularized, with blood flow penetrating from the mantle to the central core, where it then breaks into a number of fenestrated capillaries that flow past β cells to the islet mantle (Bonner-Weir, 1988; Bonner-Weir and Orci, 1982). Blood flow in islets represents ~20% of all blood that flows into the pancreas, a disproportionately large volume in that islets represent 1–2% of the pancreas volume (Bonner-Weir and Orci, 1982). Islets also contain a number of additional nonendocrine cell types including macrophages, dendritic cells, and fibroblasts (Setum *et al.*, 1991). Of these cell types, experimental evidence supports an effector role for endothelial cells and intra-islet macrophages in mediating β-cell damage during the development of autoimmune diabetes.

Figure 3 Islet cellular composition. Islets are composed of endocrine β cells (insulin-producing, ~70%), α cells (glucagon, ~25%), and a small percentage of somatostatin-secreting δ cells and polypeptide-secreting cells. Islets also contain a limited number of endothelial cells, macrophages, dendritic cells, and fibroblasts.

Cellular Source of iNOS in Islets

β Cells

Central to understanding the mechanisms by which nitric oxide impairs β-cell function is the identification of the islet cellular sources of iNOS. This is a particularly important issue in that β cells are selectively destroyed during the development of autoimmune diabetes, whereas other islet cell types remain unharmed (Bach, 1994). As a potential mechanism to explain β-cell-selective destruction in autoimmune diabetes, we examined whether cytokine-stimulated iNOS expression is selective for β cells. In these studies, primary β cells were purified from rat islets by fluorescence activated cell sorting (FACS). Islet cell purification by FACS results in an ~95% pure population of β cells and an ~85% pure population of α cells (Pipeleers *et al.*, 1985). Treatment of FACS-purified β cells for 24 hours with IL-1 results in iNOS expression and nitric oxide production, an inhibition of glu-

glucose oxidation, and an inhibition of glucose-stimulated insulin secretion (Corbett *et al.*, 1992b; Eizirik *et al.*, 1992; Strandell *et al.*, 1995). L-NMMA and AG prevent IL-1-induced nitrite formation and also the inhibitory actions of this cytokine on glucose oxidation and insulin secretion (Corbett *et al.*, 1992b). Importantly, IL-1 fails to inhibit glucose oxidation or stimulate iNOS expression by primary α cells purified by FACS (Corbett *et al.*, 1992b). Immunohistochemistry was used to confirm that β cells are the sole islet cellular source of iNOS in response to IL-1. As shown in Fig. 4, IL-1 stimulates high levels of iNOS expression (red fluorescence) in insulin-containing cells (green fluorescence) as evidenced by the intense yellow fluorescence on double exposure (Corbett and McDaniel, 1995). Importantly, not all insulin-containing cells express iNOS, and iNOS expression was not detected in non-insulin-containing cells. These findings show that the β cell is the sole islet cellular source of iNOS in response to IL-1, and β -cell production of nitric oxide results in impairment of β -cell function.

Human islets are similar to rat islets in that β cells are the major cellular source of iNOS in response to IL-1 plus IFN- γ . In human islets treated for 40 hours with IL-1 plus IFN- γ , iNOS and insulin immunoreactivity colocalize (Arnush *et al.*, 1998a). However, iNOS expression is also observed in a limited population of islet cells that do not contain insulin. These findings suggest either that a second population of islet cells other than β cells express iNOS or that the iNOS positive cells which do not contain insulin are actually β cells that have been depleted of insulin stores. Whereas human islet insulin content is reduced during culture, it is likely that this second population of iNOS-positive cells in human islets is islet ductal cells. Pavlovic *et al.* (1999a) have shown that IL-1 plus IFN- γ stimulates iNOS mRNA accumulation

and nitrite production by a partially purified population of ductal cells isolated from human pancreata. In addition, iNOS expression localizes with cytokeratin-19, a ductal cell-specific marker (Pavlovic *et al.*, 1999a). These findings indicate that both β cells and ductal cells are sources of iNOS in human islets treated with IL-1 plus IFN- γ .

Endothelial Cells

Islets are highly vascularized in that 8–10 β cells surround an islet capillary, which is composed of a single layer of endothelial cells. It is possible to obtain cultures of pure islet endothelial cells from isolated rat islets by outgrowth onto a collagen matrix. The phenotype of islet endothelial cells differs from exocrine and aortic endothelium in that islet endothelial cells express high levels of the OX2 antigen (specific for thymocyte and brain endothelium), whereas the exocrine and aortic endothelial cells stain weakly for this antigen (Suschek *et al.*, 1994). Treatment of rat islet endothelial cells with a combination of IL-1 plus TNF plus IFN- γ stimulates nitric oxide production, as evidenced by increased nitrite production and the formation of EPR-detectable iron–nitrosyl complexes in these cells (Suschek *et al.*, 1994). Importantly, coculture of activated islet endothelial cells (following cytokine treatment) with islet cells at a target to effector ratio of 1:1 results in islet cell death as determined by trypan blue exclusion, DNA damage by terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end-labeling (TUNEL) staining, and morphological damage by electron microscopy (Steiner *et al.*, 1997). Under these conditions, islet cell death is dependent on endothelial cell production of nitric oxide. L-NMMA prevents activated endothelial cell-mediated islet cell death, and resident non-

Figure 4 Immunohistochemical analysis of iNOS expression in rat islets in response to IL-1. Rat islets were treated for 40 hours with IL-1, fixed, and used to prepare thin sections. Insulin (green) and iNOS (red) expression was evaluated by immunofluorescence. IL-1 stimulates iNOS expression in insulin-containing cells (yellow). Arrows indicate a limited number of β cells that fail to express iNOS in response to IL-1. These data demonstrate that β cells are the sole islet cellular source of iNOS in response to IL-1 stimulation. Reproduced from the *J. Exp. Med.* **181**, 559–568 (Corbett and McDaniel, 1995) by copyright permission of The Rockefeller University Press. See color insert.

activated islet endothelial cells fail to kill islet cells (Steiner *et al.*, 1997). These findings indicate that islet endothelial cells are a potential source of nitric oxide that may damage β cells during the development of autoimmune diabetes.

Islet endothelial cells are also unique in that endothelial NOS (eNOS) enzymatic activity is dependent on glucose. In a concentration-dependent manner, glucose stimulates islet eNOS activity and nitric oxide production (Suschek *et al.*, 1994). This concentration dependence is similar to the concentration-dependent effects of glucose on insulin secretion. In contrast, aortic endothelial cell eNOS activity is not dependent on the ambient glucose concentration (Suschek *et al.*, 1994). The physiological relevance of the glucose-dependent eNOS activation in islet endothelial cells is unclear. Evidence suggests that nitric oxide may modulate blood flow in islets (Jansson and Andersson, 1997) and may also participate in the regulation of the initial phase of glucose-stimulated insulin secretion (Spinas *et al.*, 1998). However, eNOS regulation of islet blood flow is complex in that islet capillaries do not contain an underlining layer of smooth muscle cells or pericytes that appear to regulate blood flow in capillaries or in capillary beds (Hickey and Kubes, 1997; Kubes, 1995).

Functional defects in islet endothelial eNOS activity also correlate with the probability of diabetes development in the BB rat. In this model of diabetes, diabetes-prone (dp) BB rats naturally develop diabetes, whereas diabetes-resistant (dr) BB rats do not spontaneously develop disease (Kastern *et al.*, 1990). Suschek *et al.* (1999) have shown that islet endothelial cells isolated from dpBB and drBB rats fail to produce nitric oxide in a glucose-dependent manner. In addition, the level of nitric oxide produced by dpBB rat islet endothelial cells is three- to fourfold lower than the levels produced by endothelial cells isolated from drBB and Wistar rat islets. Although islet endothelial cell eNOS activity is impaired, the eNOS activity of aortic endothelial cells isolated from dpBB and drBB rats does not display similar defects (Suschek *et al.*, 1999). These novel findings are significant in that early functional and morphological changes in the islet vasculature resulting in an increased permeability have been suggested to facilitate extravasation of inflammatory cells into islets. Because nitric oxide inhibits leukocyte adhesion (Hickey and Kubes, 1997), a reduced capacity of islet endothelial cells to produce nitric oxide, as observed in the BB rat, may enhance both inflammatory cell adhesion and infiltration of these cells into islets. Consistent with this interpretation, pharmacological reductions in vascular permeability have been shown to attenuate diabetes development induced by multiple injections of low doses of streptozotocin in mice (Schwab *et al.*, 1986). These important observations suggest that islet endothelial cell nitric oxide production may play a primary role in the regulation of inflammatory cell adhesion and infiltration into islets during diabetes development.

MACROPHAGES

Macrophages are known to kill islet cells in a nitric oxide-dependent manner. Kroncke *et al.* (1991a) first showed that

incubation of activated macrophages with islet cells at a target to effector ratio of 2:1 results in islet-cell destruction in a nitric oxide-dependent manner. Islet-cell destruction appears to be due to macrophage production of nitric oxide and not cytokine-induced iNOS expression by islet cells, in that antibody neutralization of the macrophage-derived cytokines IL-1 or TNF does not prevent activated macrophage-mediated islet-cell damage (Kroncke *et al.*, 1991a, b). These studies provided the first evidence that islet cells are sensitive to nitric oxide produced by activated macrophages. Importantly, macrophages are one of the first cell types to infiltrate islets during the progression of autoimmune diabetes (Hananberg *et al.*, 1989; Signore *et al.*, 1989; Yoon *et al.*, 1998), suggesting that increased production of nitric oxide by these inflammatory macrophages may represent an effective mechanism for mediating β -cell destruction.

Although macrophages infiltrate islets during the progression of autoimmune diabetes, islets also contain a limited number of resident macrophages, ~ 10 – 15 per islet (or $\sim 0.5\%$ of islet cells) (Arnush *et al.*, 1998b; Lacy and Finke, 1991; Setum *et al.*, 1991). This resident population of macrophages has been proposed to participate in the initial events leading to β -cell damage and the development of autoimmunity directed against β cells (Lacy, 1994). Multiple lines of evidence support this hypothesis. It has been shown that incubation of isolated mouse islets with high concentrations of IFN- γ for 5 days results in islet degeneration. Depletion of MHC class II-expressing cells (including macrophages) by a 7-day culture at 24°C prevents IFN- γ -mediated islet degeneration (Lacy and Finke, 1991). Second, autoimmune diabetes induced by multiple injections of low doses of the β -cell toxin streptozotocin in CD-1 mice is attenuated by feeding these mice a diet deficient in essential fatty acids (Wright *et al.*, 1988). Third, this diet deficient in essential fatty acids also attenuates the natural progression of diabetes in dpBB rats (Lefkowitz *et al.*, 1990). Importantly, the fatty acid-deficient diet has been shown to deplete tissue macrophages (Lefkowitz *et al.*, 1987), suggesting that the protective effects of this diet on the development of autoimmune diabetes may be associated with the depletion of resident macrophages (Wright *et al.*, 1988; Lacy, 1994).

Other studies have examined the biochemical mechanisms by which resident islet macrophages mediate β -cell damage. Treatment of rat islets for 24 hours with TNF plus LPS, classic conditions used to activate macrophages, results in the formation of nitrite and an inhibition of insulin secretion, effects that are prevented by L-NMMA and AG (Arnush *et al.*, 1998b; Corbett and McDaniel, 1995). Importantly, TNF plus LPS fails to inhibit glucose-stimulated insulin secretion or stimulate nitrite formation by primary β cells purified by FACS, indicating that the inhibitory actions of TNF plus LPS on rat islet function are not mediated by a direct action of these agents on β cells (Corbett and McDaniel, 1995). Because activated macrophages release IL-1 in addition to producing nitric oxide, the potential role of IL-1 in mediating the inhibitory actions of TNF plus LPS on insulin secretion by rat islets was examined using the interleukin 1 receptor antagonist protein (IRAP). IRAP is a member of the

IL-1 family of cytokines that prevents IL-1 signaling by competing with IL-1 for receptor binding (Arend, 1993; Arend *et al.*, 1998). As shown in Fig. 5, IRAP prevents TNF plus LPS-induced nitrite formation and the inhibitory actions of these agents on glucose-induced insulin secretion. These findings suggest that TNF plus LPS mediates β -cell damage by stimulating the local release of IL-1 in islets and that IL-1 attains sufficient levels in islets to stimulate β -cell damage in a nitric oxide-dependent fashion. Although TNF plus LPS fails to stimulate iNOS expression by FACS-purified β cells, β cells are the primary islet cellular source of iNOS in response to TNF plus LPS. As shown in Fig. 6, TNF plus LPS stimulates iNOS expression (red fluorescence) primarily in insulin-containing cells (green fluorescence) as evidenced by the yellow fluorescence on the double exposure. Consistent

with the requirement for IL-1, IRAP significantly reduces the number of islet cells that express iNOS in response to TNF plus LPS, and the few remaining iNOS-positive cells do not contain insulin (Corbett and McDaniel, 1995).

Immunological and biochemical evidence was used to identify macrophages as the islet cellular source of IL-1 in response to TNF plus LPS. As shown in Fig. 5, depletion of tissue macrophages by culturing islets for 7 days at 24°C (Lacy and Finke, 1991) prevents TNF plus LPS-induced iNOS expression, nitrite production, and inhibition of insulin secretion (Arnush *et al.*, 1998b). Also, macrophage depletion prevents TNF plus LPS-induced IL-1 α and IL-1 β mRNA accumulation in rat islets (Arnush *et al.*, 1998b). The isoform of IL-1 that is released in islets and that mediates rat islet damage in response to TNF plus LPS appears to be

Figure 5 Activated resident macrophages mediate β -cell damage by the local release of IL-1. Treatment of freshly isolated rat islets (a) with TNF plus LPS results in the inhibition of glucose-stimulated insulin secretion and nitric oxide formation, effects that are prevented by IRAP. Depletion of resident macrophages (b) prevents the inhibitory actions of TNF plus LPS on glucose-stimulated insulin secretion by rat islets and prevents the stimulatory effects on nitrite production. These findings show that activation of macrophages results in an inhibition of β -cell function that is mediated by the local release of IL-1 in islets. Reproduced with permission from *J. Immunol.* **160**, 2684–2691 (Arnush *et al.*, 1998b), copyright 1998 by The American Association of Immunologists.

Figure 6 Immunohistochemical analysis of iNOS expression in rat islets treated with TNF plus LPS. Rat islets were treated for 40 hours with TNF plus LPS or TNF plus LPS plus IRAP, fixed, and used in preparation of thin sections. Insulin (green) and iNOS (red) expression was evaluated by immunofluorescence. TNF plus LPS stimulates iNOS expression by ~50% of islet cells, and this expression localizes with insulin-containing cells (yellow on double exposure). IRAP prevents β -cell expression of iNOS, but it does not inhibit iNOS expression by a subpopulation of islet macrophages. Reproduced from the *J. Exp. Med.* **181**, 559–568 (Corbett and McDaniel, 1995) by copyright permission of The Rockefeller University Press. See color insert.

IL-1 β , as antibody neutralization of IL-1 β prevents TNF plus LPS-induced nitrite production by rat islets (Arnush *et al.*, 1998b). Confirmation that macrophages are the islet cellular source of IL-1 β in response to TNF plus LPS was obtained by immunohistochemical localization of IL-1 β with the macrophage surface marker ED1 (Arnush *et al.*, 1998b).

If tissue macrophages participate in the development of insulin-dependent diabetes mellitus, then activation of this cell population in human islets should impair β -cell function. The combination of TNF plus LPS plus IFN- γ stimulates iNOS expression, stimulates nitrite formation, and inhibits glucose-stimulated insulin secretion by human islets (Arnush *et al.*, 1998a). IRAP attenuates the inhibitory actions of TNF plus LPS plus IFN- γ on glucose-stimulated insulin secretion, and it prevents the stimulatory actions of this combination of cytokines and endotoxin on iNOS ex-

pression and nitrite production (Arnush *et al.*, 1998a). These findings are consistent with studies in rat islets and show that IL-1 released locally in human islets impairs human islet function. AG also attenuates the inhibitory actions of TNF plus LPS plus IFN- γ on insulin secretion and completely prevents nitric oxide production, indicating that nitric oxide mediates, in part, the impairment in β -cell function under these conditions (Arnush *et al.*, 1998a). Macrophages appear to be the cellular source of IL-1 in human islets treated with TNF plus LPS plus IFN- γ . Depletion of MHC class II-positive cells by culturing for 7 days at 24°C prevents TNF plus LPS plus IFN- γ -induced iNOS and IL-1 expression and nitrite formation by human islets. Also, immunohistochemical localization of IL-1 β with the human macrophage marker CD68 in human islet cells treated with TNF plus LPS plus IFN- γ provides direct evidence that macrophages are the

human islet cellular source of IL-1 β (Arnush *et al.*, 1998a). In contrast to studies performed in rat islets, tissue macrophage activation in human islets also requires IFN- γ in addition to TNF plus LPS. Presently, it is not clear if IFN- γ is required to activate tissue macrophages to release IL-1 or to stimulate iNOS expression by β cells (human β cells require both IL-1 and IFN- γ for iNOS expression), or if IFN- γ participates in both events.

The studies just outlined provide biochemical and immunological evidence to support a novel mechanism by which resident islet macrophages mediate β -cell damage (Fig. 7) (McDaniel *et al.*, 1996). Activation of resident islet macrophages results in the expression and release of IL-1 in the microenvironment of islets. IL-1 attains a concentration in this microenvironment that is sufficient to stimulate iNOS expression by β cells (IFN- γ is also required for iNOS expression by human β cells). Under these conditions, β -cell production of nitric oxide mediates the inhibitory actions of activated macrophages on β -cell function. Importantly, these findings address two important and controversial issues. First, these findings provide biochemical evidence to support the hypothesis that tissue macrophages may play a critical role in precipitating events that trigger the initial destruction of β cells during the development of autoimmune diabetes (Lacy, 1994). Second, these findings address a controversy concerning human macrophage production of nitric oxide. It is clear that human macrophages express iNOS (Albina and Reichner, 1998; MacMicking *et al.*, 1997); however, the level of nitric oxide produced by human macrophages is much lower than the level produced by rodent macrophages (Albina, 1995). The importance of nitric oxide in disease progression has been questioned because of this reduced

capacity of human macrophages to produce nitric oxide (Albina, 1995). The studies outlined earlier suggest that nitric oxide may participate in the development of human disease; however, the source of nitric oxide may not be macrophages, but target cells, activated by cytokines released locally by tissue macrophages. In type I diabetes mellitus, the findings described earlier suggest that human macrophages may regulate target β -cell expression of iNOS and production of nitric oxide by releasing IL-1 locally in islets, and that β -cell production of nitric oxide results in an impairment in β -cell function.

Transcriptional Regulation of iNOS Expression by β Cells

A number of transcriptional regulators have been implicated in the regulation of iNOS expression, and this regulation appears to be both species and cell type specific (Förstermann and Kleinert, 1995; Taylor *et al.*, 1998; Wang and Marsden, 1995). Of these regulators, nuclear factor κ B (NF- κ B) appears to be essential for cytokine-stimulated iNOS expression by β cells (Eizirik *et al.*, 1996a). NF- κ B is a ubiquitously expressed protein composed primarily of p50 and p65 subunits that is found sequestered in the cytosol of unstimulated cells by its inhibitor protein, I κ B (Baeuerle and Henkel, 1994; Ghosh, 1999). On stimulation, I κ B is phosphorylated on specific serine residues, ubiquitinated, and targeted for degradation by the 26S proteasome (Baeuerle and Henkel, 1994; Ghosh, 1999). Free of I κ B, NF- κ B translocates to the nucleus to activate gene transcription. The rat, mouse, and human iNOS promoters contain consensus sequences for two NF- κ B binding sites, one proximal and one distal to the TATA start site, and both appear to be required for maximal iNOS promoter activity in mouse macrophages (Beck and Sterzel, 1996; Chu *et al.*, 1995; Eberhardt *et al.*, 1996; Xie *et al.*, 1993). In rat insulinoma cells and rat islets, IL-1 stimulates the degradation of I κ B and stimulates nuclear localization and activation of NF- κ B (Darville and Eizirik, 1998; Flodstrom *et al.*, 1996; Kwon *et al.*, 1995; Saldeen and Welsh, 1994; Scarim *et al.*, 1998). Inhibitors of NF- κ B, diethyl dithiocarbamate (DETC) and pyrrolidinedithiocarbamate (PDTC), prevent IL-1-induced iNOS expression by RINm5F cells and rat islets (Flodstrom *et al.*, 1996; Kwon *et al.*, 1995; Saldeen and Welsh, 1994). These findings suggest that NF- κ B is required for IL-1-induced iNOS expression by β cells. Using a reporter construct containing 1.5 kb of the rat iNOS promoter, mutations in the two NF- κ B response elements prevent IL-1-induced reporter activity in transfected RINm5F cells and primary β cells (Darville and Eizirik, 1998). These findings confirm that NF- κ B plays a primary role in the regulation of iNOS expression by rat β cells in response to IL-1.

In addition to NF- κ B, the rat, mouse, and human iNOS promoter contains IFN response elements, IFN- γ response elements (γ -IRE), IFN-stimulated response elements (ISRE), and γ -activated sequence sites (GAS) (Beck and Sterzel, 1996; Chu *et al.*, 1995; Eberhardt *et al.*, 1996; Xie *et al.*,

Figure 7 Mechanism by which resident macrophages mediate β -cell damage. Activation of islet macrophages results in the expression of iNOS and IL-1. IL-1 produced by macrophages accumulates in islets to levels sufficient to stimulate iNOS expression by β cells. Production of nitric oxide by β cells mediates the inhibitory actions of activated macrophages on β -cell function. Production of nitric oxide by resident macrophages (following treatment of rat islets with TNF plus LPS plus IRAP) does not mediate β -cell damage. Reproduced with permission from *Proc. Soc. Exp. Biol. Med.* (McDaniel *et al.*, 1996) by the Society for Experimental Biology and Medicine. See color insert.

1993). IFN- γ is required, in addition to IL-1, for iNOS expression by NOD mouse and human islets (Corbett *et al.*, 1993a; Eizirik *et al.*, 1994a; Heitmeier *et al.*, 1999b; Thomas *et al.*, 1999). IFN- γ also primes for IL-1-induced iNOS expression by NOD mouse and rat islets, and it potentiates IL-1-induced iNOS expression by RIN cells and rat and human islets (Heitmeier *et al.*, 1997, 1999b). These findings suggest that IFN- γ may also play an essential role in cytokine-stimulated iNOS expression by β cells. IFN- γ activates a family of transcription factors known as the signal transducers and activators of transcription (STATs). In response to IFN- γ , STAT1 is recruited to the IFN- γ receptor, where it is phosphorylated on specific tyrosine residues by Janus kinases, JAK1 and JAK2. Thus activated, STAT1 homodimers translocate to the nucleus and activate new gene transcription by binding to consensus GAS sites (Darnell, 1998; Schindler, 1999). IFN- γ stimulates STAT1 phosphorylation and nuclear translocation in rat islets and primary rat β cells (Heitmeier *et al.*, 1999b). Also, the priming actions of IFN- γ on IL-1-induced iNOS expression by β cells are associated with prolonged nuclear localization and DNA binding activity of STAT1 (Heitmeier *et al.*, 1999b). Mutational analysis of the GAS response elements in the rat iNOS promoter significantly reduces IL-1 plus IFN- γ -stimulated iNOS promoter activity in RINm5F cells and primary β cells (Darville and Eizirik, 1998), supporting a primary role for STAT1 in mediating the priming and potentiating actions of IFN- γ on IL-1-induced iNOS expression by rat islets.

A second IFN- γ activated transcription factor, IRF-1, has been proposed to participate in iNOS expression by β cells. IRF-1 binds to ISRE sites to activate new gene transcription (Harada *et al.*, 1998; Mamane *et al.*, 1999), and it appears to be required for IFN- γ -induced iNOS expression by murine macrophages. Macrophages isolated from IRF-1-deficient mice fail to express iNOS (Kamijo *et al.*, 1994; Martin *et al.*, 1994). It has been shown that IFN- γ induces IRF-1 expression and activation in rat islets and RINm5F cells, and IRF-1 expression precedes IL-1 plus IFN- γ -induced iNOS mRNA accumulation (Akabane *et al.*, 1995; Flodstrom and Eizirik, 1997). Mutational analysis of the distal ISRE binding elements in the iNOS promoter reduces IL-1 plus IFN- γ -stimulated promoter activity by ~30% in RINm5F cells, without negatively affecting IL-1-stimulated promoter activity (Darville and Eizirik, 1998) or IL-1 plus IFN- γ -stimulated nitrite production. These findings suggest that IRF-1 may participate in IL-1 plus IFN- γ -induced iNOS expression by rat β cells. However, β cells isolated from IRF-1-deficient mice express iNOS and produce nitric oxide in response to IL-1 plus IFN- γ at levels similar to those of wild-type mice, suggesting that IRF-1 is not required for iNOS expression by β cells under these conditions (Pavlovic *et al.*, 1999b).

Cellular Signaling Mechanisms Associated with iNOS Expression by Islets

The cellular mechanisms by which cytokines stimulate iNOS expression by β cells are poorly understood. In a num-

ber of cell types, IL-1 has been shown to activate the mitogen activated protein (MAP) kinase signaling pathway, specifically p38, c-Jun NH₂-terminal kinase (JNK), and extracellular signal-related kinases (ERK1/2) (Bleich *et al.*, 1997; Larsen *et al.*, 1998; N. Welsh, 1996). In RINm5F and HIT cells, and in rat islets, IL-1 stimulates the phosphorylation of JNK and the phosphorylation and activation of p38 and ERK1/2 (Bleich *et al.*, 1997; Larsen *et al.*, 1998; N. Welsh, 1996). Pharmacological inhibitors of p38 (SB 203580) and ERK1/2 (MEK inhibitor PD 098059) attenuate and, in combination, prevent IL-1-induced iNOS expression by RINm5F cells and IL-1-induced nitrite formation by rat islets (Larsen *et al.*, 1998). In addition, inhibition of p38 also attenuates the inhibitory effects of IL-1 on media insulin accumulation from rat islets following a 24-hour culture (Larsen *et al.*, 1998). Although these studies support a role for MAP kinase activation by IL-1 in islets, additional studies will be required to determine if this signaling cascade is required for IL-1-induced iNOS expression and the damaging actions of IL-1 on β -cell function.

Does Nitric Oxide Impair β -Cell Function by Autocrine or Paracrine Mechanisms?

Nitric oxide has been shown to modulate cellular physiology by functioning as a paracrine effector molecule. The regulation of vascular tone, neuronal transmission, and macrophage-mediated immune defense relies on the ability of nitric oxide to diffuse from cells producing this free radical to target cells to mediate its action (Kerwin *et al.*, 1995; Lancaster, 1997). The question of whether nitric oxide impairs β -cell function by autocrine or paracrine mechanisms has generated interest because of the findings that activated macrophages (and endothelial cells) can kill islet cells when incubated at an effector to target ratio of 2:1 (Kroncke *et al.*, 1991a). However, in intact islets, β -cell damage only occurs under conditions in which β cells produce nitric oxide (Arnush *et al.*, 1998b; Corbett and McDaniel, 1995). For example, rat β cells are the sole islet cellular source of nitric oxide in response to IL-1, and under these conditions β -cell function is impaired. In contrast, TNF plus LPS stimulates resident islet macrophage iNOS expression and nitric oxide production; however, in the presence of IRAP (or under conditions in which the actions of locally released IL-1 are inhibited) macrophage nitric oxide production does not impair β -cell function (Arnush *et al.*, 1998b; Corbett and McDaniel, 1995). These findings can be interpreted in a number of ways. First, these findings suggest that nitric oxide may impair β -cell function in an autocrine manner, such that β cells are only sensitive to nitric oxide when they are the source of the free radical. Second, nitric oxide impairs β -cell function by paracrine mechanisms regardless of whether the source of nitric oxide is the β cell or macrophage, and the nitric oxide-mediated inhibition of β -cell function is primarily related to the levels of nitric oxide produced in islets. Third, it is possible that both mechanisms contribute to β -cell damage mediated by nitric oxide.

Islets are composed such that the majority of β cells are found in the central core, with 8–10 β cells forming a rosette-type structure surrounding an islet capillary (Bonner-Weir, 1988; Bonner-Weir and Orci, 1982). The mantle of the islet comprises primarily α cells (Bonner-Weir, 1988; Bonner-Weir and Orci, 1982). In this structure, β cells are found in close proximity, such that nitric oxide produced by one β cell may directly influence the function of adjacent β cells. The hypothesis that nitric oxide produced by β cells functions by paracrine interactions within islets and that the level of islet damage is a function of the amount of nitric oxide produced is supported by the following observations: (1) β -cell production of nitric oxide in intact islets results in a complete inhibition of insulin secretion following a 24-hour incubation (Corbett *et al.*, 1991; N. Welsh *et al.*, 1991), whereas nitric oxide produced by primary β cells purified by FACS results in only $\sim 65\%$ inhibition of insulin secretion (Corbett *et al.*, 1992b); and (2) in response to 1 unit/ml IL-1, FACS-purified β cells produce $\sim 35\%$ more nitric oxide than β cells found in intact islets [assuming that islets contain $\sim 70\%$ β cells, that on average islets produce ~ 35 pmol of nitrite per islet, and that FACS-purified β cells produce ~ 80 pmol of nitrite per islet equivalence, (Corbett and McDaniel, 1995)]. Although FACS-purified β cells produce more nitric oxide than intact islets, nitric oxide is less effective at inhibiting insulin secretion from purified β cells. In intact islets, β cells are in close contact with each other in the central core of the islet, whereas FACS-purified β cells are free floating in culture. If nitric oxide functions as a paracrine mediator, it would be predicted that the damaging actions of this free radical on β -cell function would be greater in intact islets than purified β cells (Fig. 8), because the diffusion distance that nitric oxide would travel between purified β cells in intact islets is much less than the diffusion distance between β cells free floating in culture. Conversely, if nitric oxide functions as an autocrine mediator of β -cell damage, then IL-1 should inhibit β -cell function by similar levels in both intact islets and purified β cells, because nitric oxide-mediated damage would not be dependent on diffusion of this free radical from cell to cell. These findings support a paracrine action of nitric oxide in mediating cytokine-induced inhibi-

tion of β -cell function, although these studies do not rule out the possibility that nitric oxide also functions as an autocrine inhibitor of β -cell function.

Mechanisms of Islet-Cell Death in Response to Nitric Oxide

Using isolated rodent islets, cytokines such as IL-1 and IL-1 in combination with TNF and IFN- γ have been shown to stimulate islet degeneration and islet-cell death (McDaniel *et al.*, 1996; Rabinovitch and Suarez-Pinzon, 1998; N. Welsh *et al.*, 1994). Islet degeneration is characterized by cell sloughing, loss of islet integrity, and morphological disaggregation (Corbett and McDaniel, 1994; Lacy and Finke, 1991). We have shown that IL-1 and IL-1 plus IFN- γ -stimulated islet degeneration is prevented by L-NMMA and AG, providing evidence that nitric oxide mediates islet morphological damage (Corbett and McDaniel, 1994; Heitmeier *et al.*, 1997; Lacy and Finke, 1991). Cytokine-stimulated islet-cell lysis also appears to be mediated, at least in part, by nitric oxide. Using electron microscopic analysis to evaluate islet-cell death, Kolb and co-workers have shown that islet-cell death mediated by IL-1 and activated macrophages (incubated with islet cells at an effector to target ratio of 2:1) is prevented by the inhibition of iNOS (Kroncke *et al.*, 1991a, b). Nitric oxide donor compounds also stimulate islet-cell death (Cunningham and Green, 1994; Delaney and Eizirik, 1996; Delaney *et al.*, 1996; Hadjivassiliou *et al.*, 1998). Although nitric oxide (supplied exogenously using nitric oxide donor compounds) kills islet cells, cell death is not selective, as both α and β cells are destroyed (Kroncke *et al.*, 1991a). Functionally, islet-cell death is characterized by an inhibition of islet oxidative metabolism and DNA damage. We and others have shown that the exogenous addition of nitric oxide as well as nitric oxide produced following cytokine stimulation of islets results in the inhibition of glucose oxidation to CO_2 , and aconitase activity (Mandrup-Poulsen, 1996; McDaniel *et al.*, 1996; Rabinovitch and Suarez-Pinzon, 1998; Sandler *et al.*, 1991). Nitric oxide also has been shown to induce islet-cell DNA strand breaks as assessed by TUNEL staining, agarose gel electrophoresis, and the comet assay (Delaney and Eizirik, 1996; Delaney *et al.*, 1997; Dunger *et al.*, 1996; Hadjivassiliou *et al.*, 1998; Rabinovitch *et al.*, 1994a). These studies clearly show that cytokine-mediated islet-cell death and morphological damage are mediated by nitric oxide (Mauricio and Mandrup-Poulsen, 1998).

Central to the issue of islet-cell death in response to cytokines and nitric oxide is whether islet cells die by apoptotic or necrotic mechanisms. Apoptosis, defined as programmed cell death, is characterized by both morphological and biochemical changes, which include cell shrinking, membrane blebbing, nuclear condensation, and apoptotic body formation (Hart *et al.*, 1996; McConkey, 1998; Samali *et al.*, 1996). The net outcome of this energy-dependent mechanism of cell death is the packaging of cellular contents into

Figure 8 Does nitric oxide inhibit insulin secretion by autocrine or paracrine mechanisms? The β cells in intact islets are in close proximity, such that the diffusion distance nitric oxide would have to travel to impair the function of adjacent β cells is minimal. However, the diffusion distance that nitric oxide would have to travel to impair the function of an adjacent β cell is much larger in culture because the cells are free floating.

membrane-bound vesicles that are phagocytized in the absence of an inflammatory response (Nicotera *et al.*, 1999). In contrast, the loss of cell membrane continuity, membrane rupture, and leakage of cellular contents characterize necrosis (McConkey, 1998). In many cases necrosis results in acute inflammation (McConkey, 1998). The inflammatory cytokine IL-1 has been shown to induce DNA fragmentation in RINm5F cells in a NO-dependent manner, and IL-1, TNF, nitric oxide donor compounds, peroxynitrite, and oxygen radicals have been shown to stimulate DNA fragmentation in isolated rodent islets (Delaney *et al.*, 1993, 1997; Dunger *et al.*, 1996; Eizirik *et al.*, 1996b; Fehsel *et al.*, 1993; Rabinovitch *et al.*, 1994a). Apoptosis is an energy-requiring event, and nitric oxide (either from donor compounds or cytokine-induced NO production) is a potent inhibitor of mitochondrial oxidation, resulting in a reduction in cellular levels of ATP. Therefore, although nitric oxide-mediated islet-cell death displays a number of apoptotic features, mainly DNA damage, in the absence of functional mitochondria and energy-rich ATP, it is difficult to conclude that cytokine-induced islet-cell death is strictly by apoptosis. Apoptotic cell death is also associated with the activation of a family of aspartic proteases, termed caspases, that execute virtually all forms of apoptosis (Rathmell and Thompson, 1999). Although islets have been shown to express members of the caspase family of proteases (Ingelsson *et al.*, 1998; Rathmell and Thompson, 1999; Stephens *et al.*, 1997), caspase activation in islet cells in response to either nitric oxide or cytokines has yet to be established. In fact, studies have shown that nitric oxide inhibits caspase activation (Dimmeler *et al.*, 1997; Kim *et al.*, 1997; Li and Billiar, 1999). This evidence suggests that nitric oxide, either produced following cytokine stimulation or supplied exogenously to islet cells, does not stimulate islet-cell death by apoptosis, but most likely by necrosis.

The mechanism by which cytokines mediate human islet damage is more complex, as a number of studies have shown that cytokine-induced DNA damage occurs by mechanisms that are independent of nitric oxide production (Delaney *et al.*, 1997; Rabinovitch *et al.*, 1994b). It has been shown that N^G -nitro-L-arginine and L-NMMA prevent cytokine-induced nitric oxide production by human islets but fail to prevent IL-1 plus TNF plus IFN- γ -induced DNA strand breaks following prolonged exposure of 6 and 9 days (Delaney *et al.*, 1997). In addition, this study also used propidium iodide and Hoechst 33342 staining to provide additional evidence for cytokine-mediated islet-cell apoptosis by mechanisms that are independent of human islet production of nitric oxide (Delaney *et al.*, 1997). Also, prolonged exposure of human islets for 3–4 days with IL-1 plus TNF plus IFN- γ stimulates human islet DNA damage independent of nitric oxide production (Rabinovitch *et al.*, 1994b). These studies suggest that prolonged exposure of human islets to cytokines results in DNA damage that appears to be nitric oxide independent. Cytokines have also been shown to stimulate increases in intracellular levels of Ca^{2+} in islet cells (Borg and Eizirik, 1990; McDaniel *et al.*, 1988), and increased intra-

cellular levels of Ca^{2+} in β cells have been shown to stimulate β -cell apoptosis (Bai *et al.*, 1999; Zhou *et al.*, 1998). Also, serum deprivation induces insulinoma cell apoptosis (Mizuno *et al.*, 1998). Importantly, as islets utilize growth factors and nutrients in the culture medium during prolonged cytokine exposure (4–9 days), this could result in apoptosis similar to the effects of serum deprivation in insulinoma cells. Thus, in human islets, cytokine-induced nitric oxide-independent apoptosis may be associated with either increased intracellular levels of Ca^{2+} , loss of growth factors due to extended culture required for cytokine-induced human islet-cell apoptosis, or a combination of both pathways.

The mechanism by which DNA strand breaks result in islet-cell death appears to be associated with the activation of poly(ADP-ribose) polymerase (PARP). Okamoto and co-workers first proposed in 1981 that PARP may be responsible for β -cell death induced by DNA damage (Yamamoto *et al.*, 1981). PARP catalyzes the NAD^+ -dependent addition of ADP-ribose to nuclear proteins following activation. In the Okamoto model, DNA strand breaks stimulate PARP activation, and the subsequent depletion of NAD^+ results in the depletion of ATP in an effort to replenish NAD^+ levels. Kolb and co-workers have shown in isolated islets that DNA damage induced by nitric oxide (both cytokine-induced endogenous production or NO supplied exogenously by donor compounds), oxygen radicals, and the β -cell toxin streptozotocin stimulates islet PARP activity (Heller *et al.*, 1995; Radons *et al.*, 1994). Inhibition of PARP using nicotinamide or 3-aminobenzamide prevents islet-cell lysis stimulated by nitric oxide. Importantly, three independent studies have shown that PARP-deficient mice are resistant to the development of streptozotocin-induced diabetes (Burkart *et al.*, 1999; Masutani *et al.*, 1999; Pieper *et al.*, 1999). Streptozotocin is a selective β -cell toxin that induces DNA damage possibly by releasing nitric oxide during decomposition (Kwon *et al.*, 1994; Turk *et al.*, 1993). Importantly, the studies just outlined provide direct evidence to support the Okamoto model of β -cell damage during the development of autoimmune diabetes, and they provide mechanistic information on how nitric oxide-induced DNA damage may mediate cell lysis.

Recovery from Nitric Oxide-Mediated Damage

Although the studies outlined earlier show that cytokines stimulate β -cell damage in a nitric oxide-dependent manner, islets also possess the ability to recover from nitric oxide-mediated damage. The inhibitory actions of a 15-hour incubation of rat islets with IL-1 were shown to require a 4-day incubation in the absence of this cytokine to recover normal glucose-stimulated secretory function (Comens *et al.*, 1987; Helqvist *et al.*, 1991). Importantly, the time required for islets to completely recover from the inhibitory actions of IL-1 can be reduced from 4 days to 8 hours by simply inhibiting iNOS activity. In these experiments, the addition of L-NMMA or AG to islets treated for 18 hours with IL-1 and

continued culture in the presence of both IL-1 and L-NMMA or AG result in a time-dependent recovery of insulin secretion that is complete in 8 hours (Corbett and McDaniel, 1994). The recovery of insulin secretion correlates with a similar time-dependent recovery of aconitase activity that is also complete in 8 hours (Corbett and McDaniel, 1994). The ability to recover from cytokine-mediated damage is not restricted to rat islets, as L-NMMA stimulates the recovery of human islet aconitase activity inhibited by an 18-hour incubation with IL-1 plus IFN- γ (Scarim *et al.*, 1997). These findings provide evidence that by simply inhibiting iNOS activity, islets can recover from the damaging actions of IL-1 (and IL-1 plus IFN- γ for human islets) on insulin secretion and mitochondrial oxidative metabolism.

Although islets have the ability to recover from cytokine-mediated damage, prolonged exposure of islets to this cytokine results in irreversible damage. Islets treated for periods shorter than 36 hours maintain the ability to recover from IL-1-induced damage; however, exposure of islets to IL-1 for periods longer than 36 hours results in irreversible inhibition of insulin secretion and aconitase activity (Scarim *et al.*, 1997). Consistent with the irreversible inhibition of aconitase activity and insulin secretion, islets incubated for 36 hours or longer are committed to degeneration. These studies show that islets have the ability to recover from cytokine-mediated damage; however, if β cells produce nitric oxide for periods greater than 36 hours, islets are committed to destruction.

The ability of islets to recover from cytokine-mediated damage appears to be an active process that requires new mRNA transcription. The transcriptional inhibitor actinomycin D prevents L-NMMA-induced recovery from IL-1-mediated inhibition of insulin secretion and aconitase activity by rat islets (Corbett and McDaniel, 1994; Scarim *et al.*, 1998). The stimulus for the recovery process appears to be nitric oxide. Incubation of rat islets with the nitric oxide donor compound sodium (Z)-1-(N,N-diethylamino)diazen-1-ium 1,2-diolate (DEA-NO) for 1 hour stimulates ~65% inhibition of islet mitochondrial aconitase activity (Scarim *et al.*, 1998). Removal of DEA-NO by washing, followed by a 5-hour incubation in the absence of DEA-NO, results in a complete recovery of aconitase activity. Actinomycin D, when added during the 5-hour recovery period, completely prevents islet recovery from DEA-NO-stimulated inhibition of aconitase activity (Scarim *et al.*, 1998). These studies suggest that nitric oxide stimulates the expression of factors that participate in β -cell recovery from cytokine-induced damage.

One pathway that appears to participate in islet recovery from cytokine-mediated damage is the heat-shock response. Treatment of rat islets with IL-1 stimulates heat-shock protein (hsp) 70 expression in a nitric oxide-dependent manner (Anderson *et al.*, 1995; Hao *et al.*, 1999; Scarim *et al.*, 1998; Strandell *et al.*, 1995; N. Welsh *et al.*, 1995). Importantly, islet overexpression of hsp 70 either by liposomal delivery, by heat shock, or by transient transfection of hsp 70 prevents IL-1-induced islet and RINm5F cell damage (Bellmann *et al.*, 1995, 1996; Margulis *et al.*, 1991; Rothe and Kolb,

1999). It is unclear how hsp 70 expression stimulates recovery of islets from cytokine- and nitric oxide-mediated damage; however, induction of the heat-shock response in islets attenuates cytokine signaling. IL-1- and IL-1 plus IFN- γ -induced iNOS expression by rat and human islets, respectively, requires the activation of NF- κ B (Kwon *et al.*, 1995; Saldeen and Welsh, 1994). Following heat shock, IL-1 and IL-1 plus IFN- γ fail to stimulate NF- κ B nuclear localization and I κ B degradation (Scarim *et al.*, 1998). In addition, IL-1-induced phosphorylation of JNK is attenuated in RINm5F cells and rat islets that express hsp 70 (Maggi *et al.*, 2000). These findings indicate that nitric oxide stimulates the expression of the heat-shock response genes in islets, and that expression of heat-shock response factors in islets attenuates IL-1 signaling.

IL-1 also appears to be capable of stimulating the expression proteins that may protect islets from the damaging actions of IL-1. A20 is a zinc finger protein that has been shown to prevent TNF-induced apoptosis and proinflammatory responses in endothelial cells (Cooper *et al.*, 1996; Ferran *et al.*, 1998; Fries *et al.*, 1996; Jaattela *et al.*, 1996). More recently, IL-1 has been shown to stimulate the rapid expression of A20 in rat and human islets, and overexpression of A20 in rat islets prevents IL-1 plus IFN- γ -induced iNOS expression and nitric oxide-mediated islet damage (Grey *et al.*, 1999). Similar to heat shock, the protective actions of A20 appear to be associated with the inhibition of IL-1-induced NF- κ B activation; however, the mechanisms by which A20 prevent cytokine signaling in islets are unknown.

Manganese superoxide dismutase (MnSOD) also appears to participate in islet defense and recovery from cytokine-mediated damage. Cytokines such as IL-1, TNF, and IFN- γ , alone and in combination, stimulate the expression of MnSOD by rat insulinoma cell lines and rat and human islets (Borg *et al.*, 1992; Strandell *et al.*, 1995; N. Welsh *et al.*, 1995). Islet MnSOD expression appears to be directly regulated by cytokines, as the NF- κ B inhibitor PDTC prevents IL-1-induced iNOS expression, but fails to reduce IL-1-stimulated expression of MnSOD by RINm5F cells (Bigdeli *et al.*, 1994). Similar to the effects of heat shock and A20 on cytokine-mediated β -cell damage in islets, insulinoma cell lines overexpressing MnSOD are resistant to IL-1-mediated cell death (Hohmeier *et al.*, 1998). The protective actions of MnSOD are also associated with a reduction in IL-1-stimulated iNOS mRNA accumulation and nitrite production. Although the protective effects of heat shock and A20 are associated with an inhibition of IL-1 signaling in islets, it is not clear how overexpression of MnSOD prevents cytokine-induced iNOS expression or insulinoma cell damage.

Role of Nitric Oxide in the Development of Diabetes in Animal Models

Two animal models of IDDM, the BB rat and NOD mouse, spontaneously develop autoimmune diabetes with

characteristics similar to IDDM in humans (Buschard, 1996; Cheta, 1998). Male and female diabetes-prone (dp) BB rats develop insulinitis at 50–70 days of age, which is followed by destruction of insulin-secreting β cells and the development of clinical diabetes at 120 days (Buschard, 1996). Similar to human IDDM, the absence of insulin treatment results in ketoacidosis and death (Buschard, 1996). Through inbreeding, a diabetes-resistant (dr) strain of BB rats has been developed in which fewer than 1% develop autoimmune diabetes. Similarly, NOD mice spontaneously develop diabetes, but diabetes in this model is gender specific. Approximately 80% of the females develop insulinitis and diabetes, whereas only ~10–20% of the males develop disease (Kikutani and Makino, 1992). In these mice, peri-insulinitis is first observed at 4–6 weeks of age, and the mice progress to diabetes at 12–15 weeks of age. In contrast to the BB rat model, NOD mice are able to survive in the absence of insulin treatment for several months. In both the dpBB rat and NOD mouse models of autoimmune diabetes, insulinitis is first characterized by infiltration of monocytes or macrophages, followed by the appearance of T and B lymphocytes and natural killer (NK) cells (Burkart and Kolb, 1996; Crisa *et al.*, 1992). Destruction of β cells during the development of diabetes in BB rats and NOD mice appears to require both T lymphocytes and macrophages, as selective depletion of these cell types prevents disease progression (Bach, 1994; Lacy, 1994; Wicker *et al.*, 1986). The mechanism(s) by which T cells and macrophages mediate β -cell damage have remained elusive; however, macrophage and T-cell-derived soluble mediators, such as cytokines and nitric oxide, appear to play an important role.

In the BB rat, the expression of IL-1 β , IFN- γ , TNF, IL-12, IL-2, and iNOS in islets is observed under conditions in which insulinitis is associated with β -cell destruction (Chung *et al.*, 1997; Jiang and Woda, 1991; Kolb *et al.*, 1996; Rabinovitch *et al.*, 1996a; Zipris, 1996). Systemic administration of IL-1 β , TNF, IFN- γ , and IL-2 has been shown to delay or decrease the incidence of diabetes in BB rats (Nicoletti *et al.*, 1998; Satoh *et al.*, 1990; Sobel *et al.*, 1998; Takahashi *et al.*, 1993; Wilson *et al.*, 1990; Zielasek *et al.*, 1990). *In vitro*, treatment of isolated dpBB rat islets with IL-1 for 40 hours results in an eightfold increase in nitrite accumulation in the medium, which is inhibited by coincubation with L-NAME (Dunger *et al.*, 1996). L-NAME also prevents the inhibitory effects of IL-1 on glucose-stimulated insulin secretion by isolated dpBB rat islets, suggesting that the inhibitory effects are mediated by nitric oxide (Dunger *et al.*, 1996). Increased nitric oxide formation is also observed in macrophages isolated from dpBB rats (Lau *et al.*, 1998). These findings implicate increased cytokine expression and cytokine-induced iNOS expression and nitric oxide production in the development of diabetes in BB rats.

In vivo, increased iNOS expression correlates with the natural progression of diabetes in BB rats. Reverse transcriptase polymerase chain reaction (RT-PCR) analysis of BB rat pancreata indicate that iNOS mRNA expression is increased in prediabetic and diabetic BB rats (Kolb *et al.*, 1996; Kleemann *et al.*, 1993). Immunohistochemical colocalization of iNOS

with ED1-positive macrophages suggests that the majority of iNOS-expressing cells are infiltrating macrophages, with a smaller subset of iNOS-expressing β cells located within a proximal area of iNOS-positive macrophages (Kleemann *et al.*, 1993). Because activated macrophages express iNOS, produce nitric oxide, and release high levels of IL-1, it is possible that activated macrophages in close proximity to β cells during islet insulinitis in the BB rat may stimulate β -cell expression of iNOS by releasing IL-1 in this microenvironment. iNOS inhibitors, L-NMMA and AG, delay the onset of diabetes in BB rats by 13–15 days without altering the incidence of diabetes (Wu, 1995); however, oral administration of L-NAME reduces the incidence of diabetes in these rats (Lindsay *et al.*, 1995). In addition, prevention of spontaneous diabetes by subcutaneous insulin injection correlates with a decrease in iNOS expression (Kolb *et al.*, 1997) and nitric oxide formation (Stevens *et al.*, 1997). These findings suggest that increased iNOS expression and nitric oxide formation correlate with the development of diabetes in dpBB rats.

In NOD mice, the expression of cytokines, IL-1, TNF, IFN- γ , IL-12, and IL-18 are associated with increased iNOS expression, destructive β -cell insulinitis, and disease progression (Pilstrom *et al.*, 1995, 1997; Rabinovitch *et al.*, 1996b,c; Rothe *et al.*, 1996, 1997a; M. Welsh *et al.*, 1995). Inhibition of IL-1, by soluble IL-1 receptor or anti-IL-1 β antibodies, prevents cyclophosphamide (CY)-induced diabetes in NOD mice (Cailleau *et al.*, 1997; Nicoletti *et al.*, 1994). Diabetes is delayed in NOD mice deficient in IFN- γ (Hultgren *et al.*, 1996), and monoclonal antisera specific for IFN- γ attenuates the development of diabetes in NOD mice (Campbell *et al.*, 1991; Debray-Sachs *et al.*, 1991). Similarly, diabetes is prevented in NOD mice deficient in TNF (TNF receptor knockout) or by systemic administration of TNF at 4 weeks of age (Hunger *et al.*, 1997; Yang and McDevitt, 1994; Yang *et al.*, 1994). Attenuation of diabetes in NOD or CY-treated NOD mice by IL-18 and IL-12 antagonist IL-12p40 administration, respectively, is associated with decreased IFN- γ and iNOS expression in islets (Rothe *et al.*, 1999, 1997b). *In vitro*, IFN- γ , in combination with IL-1 β or TNF, stimulates iNOS expression and nitric oxide formation by isolated NOD mouse islets (Heitmeier *et al.*, 1999b; Thomas *et al.*, 1999). In addition, a short incubation (e.g., 30 min) of NOD mouse islets with IFN- γ primes NOD mouse islets for IL-1-induced iNOS expression and nitric oxide formation (Heitmeier *et al.*, 1999b). These findings suggest that macrophage and T-cell-derived cytokines induce iNOS expression and nitric oxide formation by NOD mouse islets *in vitro*, and increased cytokine and iNOS expression correlates with the development of diabetes *in vivo*.

Although iNOS expression correlates with disease progression in NOD mice, the exact role of nitric oxide is unclear. Inhibitors of iNOS, AG and L-NMMA, fail to prevent spontaneous diabetes in NOD mice, as does the genetic absence of iNOS (Bowman *et al.*, 1996; Pakala *et al.*, 1999). We have shown, however, that administration of AG delays the onset of diabetes induced by the adoptive transfer of splenocytes isolated from diabetic females to irradiated non-

diabetic male NOD mice (Corbett *et al.*, 1993b). Islets isolated from male mice following the adoptive transfer of splenocytes from diabetic female NOD mice produce high levels of nitric oxide and exhibit impaired insulin secretion in a time-dependent manner (Corbett *et al.*, 1993b). Immunohistochemical colocalization studies in pancreatic sections prepared from male NOD mice at day 9 after splenocyte transfer indicate that the β cell is one islet cellular source of iNOS in this animal model. iNOS immunoreactivity (red fluorescence) colocalizes with insulin-containing cells (green fluorescence), as evidenced by the yellow fluorescence on double exposure. (Fig. 9). A small number of non-insulin-containing cells, which are believed to be macrophages, also appear to express iNOS under these conditions (red fluorescent cells on double exposure, Fig. 9). Immunohistochemical analysis of inflammatory macrophages and islet cells isolated from NOD mice at the onset of diabetes indicates that 40–50% of both cell types express iNOS (Rabinovitch *et al.*, 1996c). Similar results were obtained in studies examining the immunohistochemical localization of iNOS in pancreatic sections prepared from NOD mice at diabetes onset (Reddy *et al.*, 1997, 1999). These findings indicate that iNOS is expressed and nitric oxide is produced in NOD islets during the progression to diabetes, and that inhibition of iNOS activity delays disease onset in the adoptive transfer NOD mouse model.

Incubation of islet-specific CD8⁺ T-cell clones with islets isolated from female NOD mice have been shown to kill NOD mouse islet cells, and the cell death is dependent on the extent of islet inflammation in the isolated islets (Gurlo *et al.*, 1999). In effect, this study showed that islet destruction was dependent on preexisting islet infiltrate, identified as macrophages. The iNOS inhibitor L-NIL prevents CD8⁺ T-cell killing of infiltrated islets in a concentration-dependent manner, suggesting that CD8⁺ T-cell-mediated islet destruction is dependent on nitric oxide production (Gurlo *et al.*,

1999). CD8⁺ T-cell-mediated islet destruction is also dependent on IFN- γ production, as antiserum to IFN- γ prevents T-cell-mediated islet killing. The amount of IFN- γ produced by the T-cell clones varied depending on the extent of islet macrophage infiltrate (Gurlo *et al.*, 1999). It is unclear from these studies whether macrophage production of nitric oxide directly mediates islet destruction, or whether macrophage-derived soluble mediators, such as IL-1 and TNF, mediate islet destruction by inducing iNOS expression and nitric oxide formation by β cells. Importantly, NOD mouse β cells require IFN- γ in addition to IL-1 to express iNOS (Thomas *et al.*, 1999), and the T-cell clones in the Gurlo study produce high levels of IFN- γ (Gurlo *et al.*, 1999). We have shown that local release of IL-1 in islets by resident macrophages mediates β -cell damage by releasing IL-1 in islets followed by IL-1 (or IL-1 plus IFN- γ)-induced iNOS expression by β cells (Arnush *et al.*, 1998b; Corbett and McDaniel, 1995). These results implicate nitric oxide in T-cell- and macrophage-mediated islet destruction during the development of IDDM in NOD mice, and they suggest that activated macrophages may participate in β -cell destruction either by producing nitric oxide, by releasing proinflammatory cytokines, or by both mechanisms.

Direct evidence to support the hypothesis that β -cell production of nitric oxide mediates β -cell damage leading to the development of diabetes has been obtained from a study that examined the development of diabetes in transgenic mice expressing iNOS under control of the rat insulin promoter (β -cell-specific iNOS expression). These mice have been shown to develop hyperinsulinemia within the first week of birth and develop hypoinsulinemic diabetes by 4 weeks of age (Takamura *et al.*, 1998). Importantly, diabetes develops in these mice in a nitric oxide-dependent manner, as AG administration (200 mg/kg two times daily) prevents the spontaneous development of diabetes (Takamura *et al.*, 1998). This study demonstrates that iNOS expression by β

Figure 9 Immunohistochemical analysis of iNOS expression in NOD mouse pancreata following adoptive transfer. Pancreata were isolated either from irradiated male NOD mice 9 days after the transfer of spleen cells from a diabetic female or from irradiated male control NOD mice. Insulin (green) and iNOS (red) expression was evaluated by immunofluorescence. iNOS expression is absent in islets of control NOD mice; however, iNOS is expressed in the pancreas of irradiated NOD mice 9 days after spleen cell transfer. iNOS expression localizes with insulin-containing cells (a) as well as a second population of non-insulin-containing cells believed to be macrophages (b). See color insert.

cells and β -cell production of nitric oxide induce β -cell dysfunction and death, resulting in the development of autoimmune diabetes.

Virus-Induced Diabetes and Nitric Oxide

Viruses have been implicated as one environmental factor that may initiate or trigger an autoimmune reaction that targets and destroys β cells in genetically susceptible individuals. Evidence to support this hypothesis includes (1) seasonal variation in the onset of acute IDDM, with the highest prevalence of disease in autumn; (2) anecdotal reports of a temporal association of viral infection with the onset of IDDM; (3) virus isolation from pancreata of acutely diabetic deceased patients and the identification of virus-specific IgM antibodies in newly diagnosed diabetic patients; and (4) induction of diabetes in genetically susceptible strains of mice, rats, and primates by infection with encephalomyocarditis (EMC) virus, Coxsackie B4 virus, Kilham's rat virus (KRV), rubella virus, and retrovirus (Bach, 1994; Yoon, 1990; Yoon *et al.*, 1987, 1989).

A wide array of viruses stimulate the development of autoimmune diabetes in both rat and mouse models (Bach, 1994; Rossini *et al.*, 1985; von Herrath *et al.*, 1997; Yoon, 1992; Yoon *et al.*, 1989). As a general theme, viral-induced diabetes requires genetically susceptible strains of mice or rats. This is consistent with the development of IDDM in genetically predisposed individuals. Studies have focused on effector mechanisms by which viral infection stimulates β -cell damage. KRV-induced diabetes in drBB rats appears to require macrophages, and it is associated with increased expression of the macrophage-derived cytokines IL-1 and TNF. Yoon and co-workers have shown that macrophage depletion (by treatment with liposome-encapsulated dichloromethylene diphosphonate) prevents KRV-induced diabetes in BB rats (Chung *et al.*, 1997). In addition, the development of viral-induced diabetes in BB rats correlates with increased mRNA expression of the macrophage-derived cytokines IL-12, IL-1 β , and TNF and with CD4⁺ T-cell expression of IFN- γ (Chung *et al.*, 1997).

Similar to KRV-induced diabetes in BB rats, EMC viral-induced diabetes in DBA/2 mice correlates with an increased level of IL-1 β and TNF mRNA expression in islets as determined by *in situ* hybridization of pancreatic sections (Hirasawa *et al.*, 1997). EMC viral-induced diabetes is characterized by an early infiltration of macrophages into islets followed by the presence of T cells at intermediate and late stages (Baek and Yoon, 1991). Depletion of T cells fails to alter disease progression in DBA/2 mice (Yoon *et al.*, 1985); however, macrophage depletion by treatment with anti-Mac 1 monoclonal antibodies (Hirasawa *et al.*, 1996) or silica (Baek and Yoon, 1991) prevents EMC viral-induced diabetes in DBA/2 mice.

Cytokine release followed by cytokine-induced β -cell damage is one mechanism by which macrophages may participate in the development of viral-induced diabetes. Hira-

sawa *et al.* (1997) have shown that daily administration of antiserum specific for IL-1 β or TNF- α (0.5 mg/mouse) starting on the day of viral infection attenuates EMC virus-induced diabetes in DBA/2 mice. In addition, EMC virus stimulates iNOS mRNA expression in islets at early stages of infection, and iNOS expression persists until the onset of diabetes in DBA/2 mice. Daily administration of the iNOS inhibitor AG (at 2 mg/mouse/day) significantly attenuates the development of EMC virus-induced diabetes (Hirasawa *et al.*, 1997). In combination, daily administration of AG and neutralizing antisera specific for IL-1 β and TNF is the most effective therapeutic strategy to attenuate EMC virus-induced diabetes in DBA/2 mice (Hirasawa *et al.*, 1997). These findings implicate macrophage-derived soluble mediators (IL-1 and TNF) and nitric oxide in the development of viral-induced diabetes.

It has been difficult to ascertain the mechanisms by which viral infection induces autoimmune diabetes because viruses from both RNA and DNA families (single-stranded and double-stranded viruses) have been implicated in disease onset (Bach, 1994; Yoon, 1990). One common determinant of a viral infection is the formation of dsRNA during virus replication. Many single-stranded viral RNAs also contain secondary structure that is double stranded in nature. dsRNA appears to be the active component of a viral infection that stimulates antiviral responses in infected cells, including type 1 interferon expression, nitric oxide production, macrophage IL-1 release, and a general inhibition of protein translation (Clemens, 1997; Proud, 1995; Robertson and Mathews, 1996; Williams, 1997). Importantly, *in vivo* administration of dsRNA [in the form of poly(IC)] stimulates the development of diabetes in drBB rats, and it accelerates the development of diabetes in dpBB rats (Ewel *et al.*, 1992; Sobel *et al.*, 1992, 1994).

Because macrophages appear to play a primary role in the development of virus-induced diabetes and because dsRNA appears to be an active component of a viral infection that activates the antiviral response (Clemens, 1997; Proud, 1995; Williams, 1997), we have examined the effects of dsRNA on macrophage activation. The combination of dsRNA and IFN- γ stimulates iNOS expression, nitric oxide production, and IL-1 release by primary macrophages isolated from CD-1 mice (Heitmeier *et al.*, 1998). Individually, dsRNA and IFN- γ fail to activate primary mouse peritoneal macrophages. These studies suggest that one mechanism by which viral infection stimulates macrophage activation is by dsRNA-induced iNOS expression, nitrite production, and IL-1 release in the presence of IFN- γ .

The direct effects of dsRNA and IFN- γ on iNOS expression and nitric oxide formation by rat and human islets have also been examined. Treatment of rat (Heitmeier *et al.*, 1999a) and human islets (M. R. Heitmeier and J. A. Corbett, 2000, unpublished observation) with dsRNA plus IFN- γ results in the time- and concentration-dependent expression of iNOS and production of nitric oxide. dsRNA plus IFN- γ -induced nitric oxide production by rat islets results in a potent inhibition of insulin secretion and islet degeneration.

AG prevents the inhibitory effects of dsRNA plus IFN- γ on β -cell function, indicating that the destructive effects are mediated by nitric oxide. Resident macrophage activation is not required for the inhibitory and destructive effects of dsRNA plus IFN- γ on rat islet insulin secretion and islet degeneration, as macrophage depletion (by a 7-day culture at 24°C) fails to prevent dsRNA plus IFN- γ -induced iNOS expression. In addition, dsRNA plus IFN- γ stimulates iNOS expression and nitric oxide formation by FACS-purified β cells, and this results in an inhibition of glucose-stimulated insulin secretion in a nitric oxide-dependent manner (Heitmeier *et al.*, 1999a). These findings indicate that a viral infection, or dsRNA, can directly inhibit β -cell function by stimulating β -cell production of nitric oxide.

In summary, these findings provide novel insights into potential mechanisms by which viral infection results in β -cell damage during the development of autoimmune diabetes. These studies suggest that viral infection stimulates macrophage activation, resulting in the local production of IL-1 in islets. IL-1 released locally within islets stimulates β -cell expression of iNOS. In addition, the viral replicative intermediate dsRNA also stimulates β -cell expression of iNOS in the presence of IFN- γ . β -Cell expression of iNOS and production of nitric oxide cause β -cell damage, resulting in the release of potential β -cell autoantigens leading to T-cell-dependent destruction of the remaining β cells and the development of autoimmune diabetes (Fig. 10).

Nitric Oxide and Type II Diabetes

Obesity, the most common disease in the United States, often leads to the development of type 2 diabetes. Peripheral

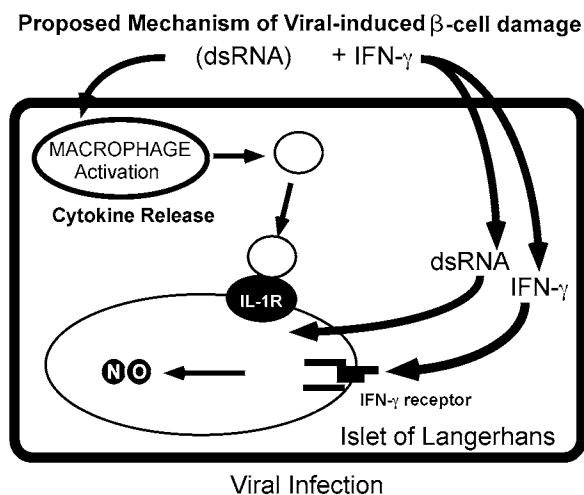

Figure 10 Mechanism of viral-induced β -cell damage. dsRNA, formed during viral replication, activates macrophages, stimulating both iNOS and IL-1 expression. IL-1, released from activated macrophages, directly stimulates β -cell expression of iNOS and production of nitric oxide. dsRNA in combination with IFN- γ is also capable of directly inducing iNOS expression by β cells. β -Cell production of nitric oxide, either in response to IL-1 released from macrophages or following the induction of iNOS in response to dsRNA plus IFN- γ , stimulates β -cell damage.

insulin resistance characterizes the initial stages of type 2 diabetes; however, normal blood glucose levels are maintained because β cells compensate by secreting increased levels of insulin (DeFronzo, 1992; Lebovitz, 1999). Diabetes develops when the β cell is no longer able to compensate for insulin resistance, resulting in elevated blood glucose levels. The mechanisms by which β cells lose their ability to compensate for the increased insulin demand are unknown; however, postmortem studies on NIDDM patients have revealed a reduction in β -cell mass (Rahier *et al.*, 1983). Much of what is known concerning β -cell damage during the development of type 2 diabetes has been obtained from the Zucker diabetic fatty rat (ZDF). These rats display prediabetic obese (7 weeks of age) and diabetic obese (14 weeks of age) stages of diabetes (Bray, 1977). β -Cell damage has been attributed to fat deposition in islets of obese diabetic ZDF rats. This "lipotoxicity" is associated with high plasma levels of free fatty acids (FFA) and with an increased capacity for lipogenesis (Unger, 1995).

Unger and co-workers (Shimabukuro *et al.*, 1997a) examined whether nitric oxide may contribute to β -cell damage in ZDF rats. Initial experiments examined the effects of FFA on the expression of iNOS and production of nitric oxide by islets isolated from prediabetic ZDF rats, from lean nondiabetic ZDF rats, and from control Wistar rats. FFA (2:1 mixture of oleate and palmitate) stimulates iNOS expression and nitrite production by islets isolated from each species of rat. However, iNOS expression and nitrite production were significantly higher in islets isolated from lean nondiabetic ZDF rats as compared to islets isolated from Wistar rats (Shimabukuro *et al.*, 1997a). Importantly, islets isolated from prediabetic ZDF rats produced the highest levels of nitric oxide in response to FFA. Functionally, FFA stimulate glucose-induced insulin secretion by islets isolated from Wistar rats, whereas they attenuate insulin secretion by islets isolated from both lean nondiabetic and prediabetic ZDF rats. The iNOS-selective inhibitor AG prevents FFA-induced nitrite production and the inhibitory actions of FFA on glucose-stimulated insulin secretion by islets isolated from both lean nondiabetic and prediabetic ZDF rats (Shimabukuro *et al.*, 1997a). In prediabetic ZDF rats, plasma FFA begin to accumulate at 7–9 weeks of age, and diabetes develops by 11–14 weeks of age (Lee *et al.*, 1994). Administration of AG to prediabetic obese ZDF rats by daily intraperitoneal injections of 400 mg/kg body weight beginning at 6 weeks of age prevents the development of diabetes and the loss of insulin immunoreactivity in islets without decreasing plasma FFA levels (Shimabukuro *et al.*, 1997a).

Regulation of FFA metabolism appears to be controlled by the action of leptin, which has been shown to inhibit esterification of FFA by enhancing intracellular oxidation (Shimabukuro *et al.*, 1998). ZDF rats are leptin resistant because of a Glu-269 to Pro mutation in the leptin receptor (Phillips *et al.*, 1996). This defect is associated with an increased triglyceride (TG) content in islets isolated from homozygous ZDF rats (*fa/fa*) (Lee *et al.*, 1997). Elevated β -cell triglyceride content has been implicated in the lipotoxicity of β cells (Shimabukuro *et al.*, 1997b). In response to IL-1,

fat-laden β cells produce greater than twofold higher levels of nitrite than wild-type control islets (Shimabukuro *et al.*, 1997c). Importantly, reductions in islet triglyceride either by adenoviral expression of the wild-type leptin receptor in β cells or by treatment with troglitazone attenuates IL-1-induced iNOS expression and islet damage in ZDF rat islets (Shimabukuro *et al.*, 1997c). These findings have been interpreted to indicate that reductions in islet TG content, by either functional leptin receptor expression in islets or by troglitazone administration, prevent β -cell lipotoxicity associated with the development of type II diabetes in ZDF rats (Shimabukuro *et al.*, 1997b,c).

Troglitazone is a high-affinity agonist of the peroxisome proliferator-activated receptor- γ (PPAR- γ). Agonists of this receptor, specifically the thiazolidenediones, are potent insulin sensitizers that are currently being used to treat insulin resistance in type 2 diabetes (Auwerx, 1999; Spiegelman, 1998; Spiegelman *et al.*, 1997; Vamecq and Latruffe, 1999; Vanden Heuvel, 1999). Naturally occurring PPAR- γ agonists such as 15-deoxy- $\Delta^{12,14}$ -prostaglandin J_2 (15-d- $\Delta^{12,14}$ -PGJ₂) and the thiazolidenediones have been shown to have anti-inflammatory properties. Troglitazone and 15-d- $\Delta^{12,14}$ -PGJ₂, as well as other PPAR- γ agonists, prevent LPS- and LPS plus IFN- γ -stimulated iNOS expression, nitrite formation, and proinflammatory cytokine expression by RAW 264.7 cells, mouse peritoneal macrophages, and microglia (Huang *et al.*, 1999; Jiang *et al.*, 1998; Petrova *et al.*, 1999; Ricote *et al.*, 1998, 1999). In addition, these PPAR- γ agonists also prevent resident macrophage IL-1 expression and release following TNF plus LPS stimulation of rat islets (Kwon *et al.*, 1999; Maggi *et al.*, 2000). Inhibition of iNOS and IL-1 mRNA transcription appears to be one mechanism by which troglitazone and 15-d- $\Delta^{12,14}$ -PGJ₂ function as anti-inflammatory agents (Jiang *et al.*, 1998; Maggi *et al.*, 2000; Ricote *et al.*, 1998). The anti-inflammatory actions of these agonists on iNOS expression suggest that the ability of troglitazone to prevent β -cell lipotoxicity in the ZDF rat islets may also be a function of the ability of this PPAR- γ agonist to inhibit iNOS expression in addition to its TG lowering actions.

Although troglitazone and 15-d- $\Delta^{12,14}$ -PGJ₂ are PPAR- γ agonists, troglitazone has a much higher affinity for PPAR- γ than 15-d- $\Delta^{12,14}$ -PGJ₂, but it is over 10-fold less effective at inhibiting iNOS expression and nitrite production by mouse peritoneal macrophages and RINm5F cells (Maggi *et al.*, 2000). These findings suggest that receptors other than PPAR- γ may mediate the anti-inflammatory actions of these agents. Consistent with this interpretation, Vaidya *et al.* (1999) have shown that the inhibitory actions of 15-d- $\Delta^{12,14}$ -PGJ₂ on the integrin-dependent oxidative burst of neutrophils are independent of PPAR- γ . In this study, 15-d- $\Delta^{12,14}$ -PGJ₂ was shown to prevent adhesion-dependent H₂O₂ production, an effect that was not modulated by a selective PPAR- γ agonist, AD-5075. In addition, AD-5075 had no effect on adhesion-dependent H₂O₂ (Vaidya *et al.*, 1999). Taken together, these studies suggest that the inhibitory actions of PPAR- γ agonists such as troglitazone and 15-d- $\Delta^{12,14}$ -PGJ₂ may be mediated by a yet to be defined receptor.

Conclusions

In this chapter, we have provided a summary of the evidence supporting a role for nitric oxide in the development of autoimmune diabetes and in β -cell damage in type 2 diabetes. It is clear from these studies that nitric oxide inhibits insulin secretion (both human and rodent) and kills β cells. Does nitric oxide mediate β -cell death during the development of autoimmune diabetes? This question has yet to be definitively addressed. Controversy concerning whether nitric oxide mediates the inhibitory effects of cytokines on human islet function continues. In addition, the development of diabetes in transgenic mice deficient in the iNOS gene has generated further skepticism. While this healthy skepticism exists, a large body of evidence supports a role for nitric oxide in the development of diabetes. Is iNOS a viable target for therapeutic intervention designed to prevent diabetes in predisposed individuals? It is too early to determine. It is clear that nitric oxide can impair β -cell function and mediate β -cell death; however, the precise stage(s) in the diabetogenic process in which nitric oxide may mediate β -cell damage and the potential roles that nitric oxide may play in the regulation of islet inflammation are unclear.

We favor an early role for nitric oxide in the development of autoimmune diabetes, functioning in the precipitating events that result in the initial damage to β cells. In this setting, β -cell damage may result in the release of autoantigens and further T-cell-dependent destruction of β cells. We also believe that macrophages may play a critical role in the regulation of iNOS expression in islets under precipitating conditions. This regulation may be by the local release of cytokines such as IL-1 and TNF in islets. In addition, islet macrophages may also participate in CD8⁺ T-cell-mediated β -cell damage that is dependent on nitric oxide production (Gurlo *et al.*, 1999). Viral infection is one precipitating event that may trigger the initial destruction of β cells during the development of autoimmune diabetes. Importantly, inhibitors of iNOS and neutralization of macrophage-derived cytokines prevent viral-induced diabetes. Although these studies provide evidence to support a role for macrophages, macrophage-derived cytokines, and nitric oxide in the development of autoimmune diabetes, continued studies into the potential roles of nitric oxide in the pathogenesis of diabetes will be required to determine whether iNOS or nitric oxide are viable therapeutic targets for disease prevention.

Acknowledgments

We thank Anna Scarim, Leonard Maggi, Naomi Miller, and Libby Blair for critical review of the manuscript. This work was supported by the National Institutes of Health Grants DK 52194 and AI 44458.

IN AUTOIMMUNE OR IMMUNE-MEDIATED DISEASES, THE IMMUNE DEFENSE SYSTEM TURNS AGAINST ITS OWN ORGANISM, SOMETIMES LEADING TO A CHRONIC AND LONG-LASTING IMBALANCE OF IMMUNE REACTIONS. IMMUNE DEFENSES ARE EITHER Th1-TYPE RESPONSES IN CONJUNCTION WITH PREDOMINANTLY CELLULAR IMMUNE REACTIONS, OR Th2-LIKE REACTIONS, MAINLY ASSOCIATED WITH HUMORAL RESPONSES. EXPRESSION OF THE INDUCIBLE NO SYNTHASE (iNOS) ALWAYS CONCURS WITH A Th1-TYPE IMMUNE REACTION, BUT THE IMPACT OF NO ON IMMUNE FUNCTION AND ITS REGULATION IS COMPLEX AND OFTEN APPEARS CONTRADICTORY. NO CAN EXERT CYTOTOXIC ACTIVITY BUT MAY ALSO PROTECT CELLS FROM A TOXIC INSULT. IT IS KNOWN TO INDUCE APOPTOSIS, BUT IT CAN ALSO EXHIBIT PROMINENT ANTI-APOPTOTIC ACTIVITY. NO ACTS LIKE AN ANTIOXIDANT BUT MAY ALSO COMPROMISE THE CELLULAR REDOX STATE VIA OXIDATION OF THIOLS SUCH AS GLUTATHIONE. NO MAY ACTIVATE SPECIFIC SIGNAL TRANSDUCTION PATHWAYS BUT IS ALSO REPORTED TO INHIBIT THEM, AND LAST BUT NOT LEAST NO MAY ACTIVATE BUT ALSO INHIBIT GENE TRANSCRIPTION. THE SITUATION APPEARS EVEN MORE COMPLICATED, AS, DEPENDING ON ITS CONCENTRATION, NO MAY REACT WITH O_2 OR O_2^- TO YIELD SPECIES THAT ARE MUCH MORE REACTIVE AND EXHIBIT A BROADER CHEMICAL REACTION SPECTRUM THAN NO ITSELF. PROLONGED iNOS ACTIVITY MAY THUS RESULT IN DIRECT CYTOTOXICITY AND LOCAL TISSUE DESTRUCTION, BUT ON THE OTHER HAND MAY ALSO SERVE TO DOWNREGULATE Th1 RESPONSES, WHICH SERVES THE IMPORTANT TASK OF LIMITING THE EXTENT OF INFLAMMATION. IN ADDITION, iNOS ACTIVITY MAY BE PROTECTIVE. THUS, THE ACTIVITY OF iNOS EXPRESSED DURING INFLAMMATORY REACTIONS HAS TO BE EVALUATED IN THE CONTEXT OF TIMING AND DURATION OF NO SYNTHESIS AS WELL AS STAGES AND SPECIFIC EVENTS IN INFLAMMATION.

Introduction

In this chapter we will outline our current understanding of the role inducible nitric oxide synthase (iNOS) plays in autoimmune or immune-mediated diseases. Our perception of the impact of NO in these illnesses has dramatically changed. We now have a much broader understanding of the role NO plays as a regulatory, protective, and destructive agent in autoimmune or immune-mediated diseases.

Definition of Autoimmunity

In order to understand the proven or possible roles of NO in autoimmune disease, a short definition of these processes is necessary. Figure 1 lists the key characteristics of autoimmunity, a process Paul Ehrlich envisaged as *Horror autotoxicus*.

First and above all, in autoimmune and immune-mediated diseases the immune defense system turns against its own body and recognizes one or several molecules as possibly hazardous, that is, it recognizes “self.” This is not dangerous per se, and it often appears to occur during local infections or other short lasting diseases. Normally, these anti-self reactivities will be rapidly downregulated and abolished. Second, the anti-self attacks have to be chronic, long-term processes in order to mediate clinically recognizable disease. Thus, the normally operating counterbalancing forces, leading to time-restricted immune responses, fail. The immune system remains locked in one state of aggression.

All of the different immune reactions operative in autoimmunity are those that work in normal immune defenses. We have to remind ourselves that there is not a special means of immune attack at work in autoimmune reactions, but rather a long-lasting imbalance of a normal response.

One important feature to distinguish autoimmune processes from other diseases is the ability to transfer the disease by antibodies or lymphocytes, for instance, to nude mice, which cannot mount an immune attack themselves. As this is not always proven or may not always be possible for various reasons, we prefer to call diseases thought to be au-

Autoimmunity (Horror autotoxicus)

- ➡ Specific immune reaction against “SELF”
- ➡ Chronic and concomitant destruction of tissue
- ➡ Principal mechanisms are identical with those used in protective immunity
- ➡ Adoptive transfer with antibodies or reactive T-lymphocytes (not always possible)

Figure 1 Main features of autoimmune diseases. Autoimmune destruction of body tissue had been envisaged by Paul Ehrlich, who named his vision *Horror autotoxicus*.

toimmune, but lacking this final proof, immune-mediated diseases.

One reason for such a failure in immune balance can be seen in local long-lasting and subclinical infections by virus or bacteria. Such an infection can be regarded as a trigger for autoimmune processes. Other factors contributing to the onset of autoimmunity are found in our environment. Thus, certain foods or exposure to ultraviolet irradiation can be regarded as environmental conditions adding to the risk for developing autoimmune diseases. However, not every person suffering from a chronic infection or exposed to environmental hazards will develop autoimmune reactions; rather, a genetic predisposition is essential for the development of disease. These reside in the major histocompatibility complex (MHC), which regulates immune responses, but genes coding for other features of normal body function outside the MHC loci are also often involved. Important risk factors contributing to the onset of self-destructive immunity are listed in Fig. 2.

Introducing the Th1/Th2 Balance

Immune defense commences in two different ways. We have long known that infections will be fought either by producing specific antibodies or by using cellular defense mechanisms. We now understand that these two different ways of immune attack can be distinguished by the different cytokines expressed. These different sets of communication-mediating proteins serve as additional signals either mounting and helping cellular defenses or steering the immune responses toward antibody production. The two states are named the Th1 response, corresponding to a cytokine profile typically found in inflammatory reactions, and the Th2 reaction, which is mainly associated with a cytokine profile driving B-lymphocyte differentiation. A list of the most prominent cytokines found in the two different states is provided in Fig. 3.

In accord with the earlier statement that autoimmune processes are normal immune reactions, albeit directed against self, we find both states of immune reaction in different autoimmune diseases. Systemic lupus erythematosus is an autoantibody-mediated disease, in contrast to insulin-dependent, “autoimmune” diabetes. In animals developing insulin-dependent autoimmune diabetes mellitus (also termed type 1 diabetes), organ destruction is invariably associated

Risk Factors

- ➡ Genetic risk factors, predominately in the MHC loci
- ➡ Additional risk factors in somatic genes
- ➡ Environmental factors
- ➡ Long-lasting sub-clinical or fulminant infections

Figure 2 Main risks that contribute to manifestation of autoimmune diseases.

Figure 3 Immune reactions can take two different routes. One type of reaction is generally named the Th1 type or inflammatory reaction that will commence by cellular reactions mostly, and during this state the cytokines listed on the left-hand side are produced. The alternative, called a Th2 type of reaction, will use antibody production predominantly and is characterized by the cytokine profile listed on the right-hand side.

with a Th1 cytokine profile. In type 1 diabetes the importance of the Th1 immune regulatory state can be demonstrated most impressively, as shown in Fig. 4. Here, in a mouse developing this disease, lymphocytes are first found around the insulin-producing islets of Langerhans in the pancreas (Fig. 4A, B). At this stage we find mostly a local expression of Th2 cytokines, and animals can remain at this stage without ever becoming diabetic. If a conversion toward a Th1 cytokine profile occurs, lymphocytes start to infiltrate the islet, and organ destruction and manifestation of the disease will result (Fig. 4C, D). This is also associated with expression of iNOS in the infiltrate. However, in human disease processes, and also in some animal models for various diseases, this Th1/Th2 imbalance is not an absolute one, and the reverse cytokines may also be expressed; they are either inefficient in counterbalancing or are time-restricted in a vain attempt to counterbalance.

After having introduced the main topics that help us to understand the immune processes at work in autoimmunity, we will now look into the role of iNOS and the local production of NO in autoimmune diseases.

Expression of iNOS as a Marker for a Th1 Cytokine Expression Profile

Expression of iNOS has been found in human immune-mediated or autoimmune diseases such as rheumatoid arthritis and multiple sclerosis, as well as in a variety of chronically inflammatory diseases of the airways, bowel, skin, blood vessels, heart, kidney, apex of the teeth, and other organs of the body (see Table I). Owing to ethical problems, data do not exist concerning iNOS expression in the most prevalent human immune-mediated disease, type 1 diabetes.

Figure 4 Autoimmunity is associated with local imbalance of the Th1/Th2 reactions. For example, in animals developing insulin-dependent diabetes, two local states of immune reaction occur. (A and B): Islets are often found with surrounding infiltrate that is not in a Th1 state [no γ -interferon (IFN- γ) (A) nor iNOS (B) expression seen], and animals can stay this way without disease; therefore, this state is also called benign insulinitis. (C and D): When immunocytes start to invade the islet and destroy the insulin-producing cells, a conversion to the Th1 state is found, as depicted by strong expression of IFN- γ (in C) and iNOS (in D). This state is also called destructive insulinitis and will lead to disease manifestation. See color insert. (Micrographs courtesy of Hubert Kolb, Düsseldorf, Germany.)

However, studies of animals developing this disease unequivocally show a role of iNOS expression for disease progression and manifestation (see Fig. 4). In all diseases associated with iNOS expression, as listed in Table I, we find a local cytokine expression profile that invariably correlates with the presence of the proinflammatory Th1-type cytokines (also compare Table I to cytokine list in Fig. 3). Although localization of iNOS immunoreactivity varies somewhat, as it is sometimes found in macrophages or in macrophage-like cells, in most cases it is associated with epithelial cells around inflammatory foci. Despite the ever-growing list of pathological conditions with iNOS expression, it is not yet known whether iNOS expression is only an epiphenomenon, due to the presence of the proinflammatory cytokines, or whether iNOS activity serves important roles. The NO produced by macrophages and epithelial cells may predominantly contribute to local destruction of tissue. Alternatively, NO can also serve to limit inflammation or local overshooting immune reactions and thus limit tissue destruction during Th1-driven immune reactions, as will be outlined in the next two sections.

Table I Local Th-1 Cytokine Production in Various Human Diseases Is Invariably Associated with iNOS Expression

Disease	Predominant cytokine profile ^a	Localization of iNOS ^b
Rheumatoid arthritis	IL-1, IL-6, IL-8, TNF- α , GM-CSF	Synovial lining cells, EC, mononuclear cells, fibroblasts, VSMC
Multiple sclerosis	IL-1, IL-2, IL-6, TNF- α , IFN- γ	M ϕ , microglia, astrocytes
Sjögren's syndrome	IL-1 β , IL-6, TNF- α , IFN- γ	Acinar and ductal epithelial cells
Asthma	IL-1 β , IL-8, TNF- α , GM-CSF	Epithelium, EC, inflammatory cells
Bronchiectasis	IL-1 β , IL-8, TNF- α	M ϕ
Idiopathic pulmonary fibrosis	IL-1 β , IL-6, IL-8, TNF- α , IFN- γ , TGF- β	M ϕ , neutrophils, airway and alveolar epithelium
Ulcerative colitis	IL-1, TNF- α , IFN- γ	Epithelial cells, inflammatory infiltrate
Crohn's disease	IL-1, TNF- α , IFN- γ	Epithelial cells, inflammatory infiltrate
Necrotizing enterocolitis	IL-6, TNF- α , IFN- γ	Epithelial cells
Celiac disease	IL-2, IL-6, TNF- α , IFN- γ	Epithelial cells, M ϕ
Psoriasis	IL-1 β , IL-8	Keratinocytes, EC, inflammatory infiltrate
Cutaneous lupus erythematosus	IL-1 β , IL-6, TNF- α	Basal epidermal layer, EC, inflammatory infiltrate
Contact dermatitis	IL-1, TNF- α , IFN- γ	EC, inflammatory cells
Atherosclerotic plaques	IL-1, IL-6, IL-12, TNF- α , IFN- γ	M ϕ , foam cells, VSMC
Dilated cardiomyopathy	IL-6, IL-8, TNF- α	Myocytes, EC, VSMC, skeletal muscle
Glomerulonephritis	TNF- α , IFN- γ	M ϕ , mesangial cells, epithelial cells
Periapical periodontitis	IL-1 β , IL-6, TNF- α , IFN- γ	Epithelial cells, EC, fibroblasts, M ϕ , PMNL
Kikuchi's disease	IL-2, IL-6, IFN- γ	Histiocytes
Systemic sclerosis	IL-1 β , IL-6, IL-8, TNF- α	EC, fibroblasts, M ϕ

^aIL, interleukin; TNF- α , tumor necrosis factor α ; GM-CSF, granulocyte macrophage colony-stimulating factor; IFN- γ , γ -interferon.

^bEC, endothelial cells; VSMC, vascular smooth muscle cells; M ϕ , macrophages; PMNL, polymorphonuclear leukocytes.

High-Output NO Synthesis Will Downregulate Local Th1 Responses

In the previous section we have seen that in various diseases the production of Th1 cytokines will be invariably associated with iNOS expression. We will now discuss the consequences of local high-output NO synthesis as far as we currently understand it. We know that the local effects of NO can be very different, ranging from cytotoxicity contributing to organ destruction, or in contrast providing protection from cell death, to altering the gene expression patterns in various cells.

NO at the site of high-output production can serve the task of self-limiting downregulation of the expression of proinflammatory cytokines, thus limiting the extent of inflammation under normal conditions. Evidence for this effect comes from two different lines of investigations. The first consists of studying the effect of NO on immune cells in *in vitro* studies. Owing to altered gene expression in the presence of NO, lymphocytes will not initiate the production of IL-2, a key cytokine for T-lymphocyte proliferation. It was also found that when IL-4, a component of the Th2 system, is upregulated by NO and the formation of the IL-12 (p40)₂ dimer, an endogenous inhibitor of IL-12 is favored. All these findings are in excellent agreement with the very early finding that the suppression of *in vitro* lymphocyte proliferation by activated syngeneic macrophages (the so-called "suppressor macrophages") is due to the NO production by these

latter cells. In Fig. 5 schematic drawings of these regulatory effects are shown. Additional support for this effect comes from examining the immune system of mice lacking a functional iNOS gene, that is, from iNOS knockout mice. These animals show a slight but consistent imbalance favoring the Th1 cytokine profile. Moreover, when backcrossing of the iNOS gene defect into animal models for various diseases, most of the Th1 diseases are unaffected, and some illnesses, especially the experimentally induced encephalitis model, show a severe exacerbation when compared to littermates with a functional iNOS gene.

In conclusion, iNOS is expressed in the presence of a proinflammatory cytokine profile (Th1 response). One of its effects is that it represents a means to downregulate the inflammation as effector in an autoregulatory feedback loop, and this loop appears to be nonfunctional in some autoimmune conditions.

High-Output NO Synthesis May Induce Local Tissue Destruction

High-output NO synthesis is currently thought to have evolved for protection of the host from infection, owing to its cytotoxic potential. However, damage of normal host cells confers on iNOS the same protective/destructive duality inherent in every major component of the protective immune response. Thus high-output NO production can result

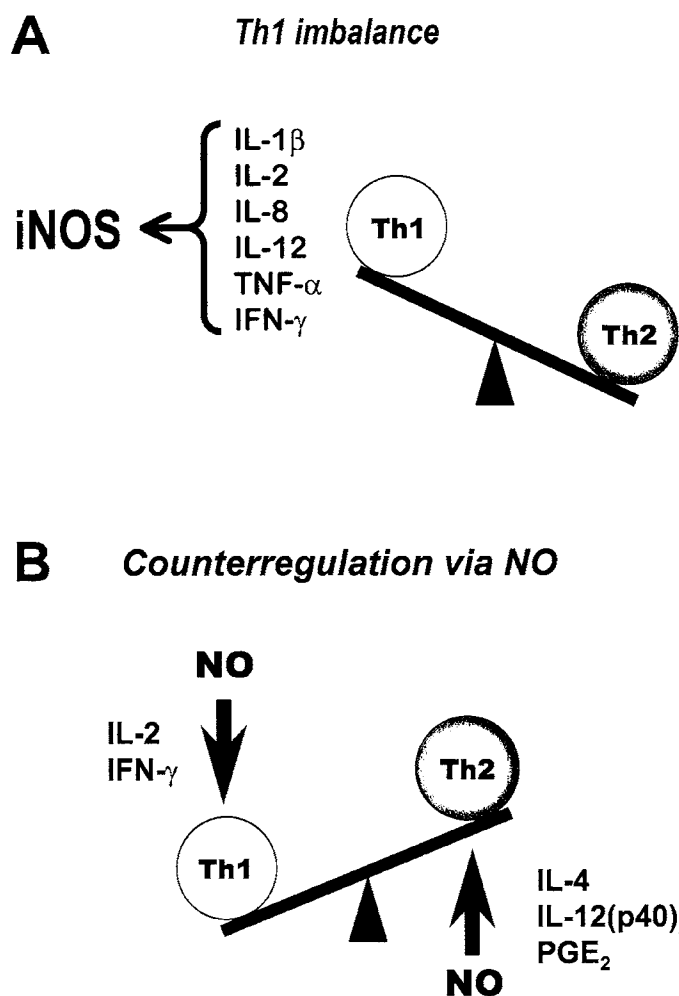

Figure 5 (A) A Th1 imbalance will induce the expression of iNOS, as most of the respective cytokines are known inducers for this enzyme. (B) On expression and functional activity of the iNOS enzyme, the NO produced will normally act as a suppressor for Th1-like activity, as it will downregulate IL-1 β and IFN- γ as well as upregulate IL-4, the endogenous IL-12 inhibitor IL-12(p40)₂, as well as prostaglandin E₂ (PGE₂). It appears that in prolonged states of chronic imbalance this feedback loop is faulty in function.

in direct cytotoxicity toward tumor cells and diverse infectious agents, but at sites of prolonged iNOS expression the neighboring tissue is also exposed to its cytotoxic activity.

Cell types that are particularly sensitive toward NO include a large subpopulation of thymocytes, certain neurons, pancreatic β cells (which produce the hormone insulin), and, of note, the macrophages themselves. In animal models of type 1 diabetes, macrophages are found within the islets activating the T-cell response according to the Th1 cytokine profile (see Fig. 4). Immunohistochemical staining for iNOS in islets with ongoing tissue destruction reveals positively stained macrophages and endothelial cells. In the same islets, pancreatic cells stain positive for DNA strand breaks (Fig. 6). As a further indication that NO produced by iNOS indeed contributes to disease manifestation, *in vitro* investigations have shown the following: (i) activated syngeneic macro-

Figure 6 (A) In pancreatic tissue sections of prediabetic rats, an iNOS-specific antiserum detects iNOS-expressing macrophages and endothelial cells in the islets of Langerhans. (B) The dark brown staining in some cells indicates DNA strand breaks as an early marker for cell death. See color insert.

phages effectively kill islet β cells, and this process is arginine dependent and can be inhibited by arginine analogs; (ii) incubation with various NO donor agents will show exactly the same result with the identical morphology, proving that NO alone suffices for islet cell killing; (iii) endothelial cells isolated and cultured from islet capillaries will also effectively kill β cells, if they had been challenged to express iNOS prior to coculture with the hormone-producing cells; and finally (iv) feeding mice developing the disease with an arginine analog in the drinking water will suspend this process, even though all the destructive infiltrating immune cells are sitting within the islets.

Another killing effect of iNOS that may also contribute to immune imbalance in autoimmunity is found in the thymus, the organ where the decisive steps of T-lymphocyte maturation and selection occur. Again, a large subpopulation of the developing T cells within the thymus are highly susceptible to NO-induced cell death. On a systemic challenge,

as with circulating lipopolysaccharide (LPS), thymic endothelia and some macrophages become positive for iNOS, and simultaneously large numbers of thymocytes will undergo apoptosis and cell death (Fig. 7). Again, *in vitro* studies confirm the effector function of endothelial cells. Such a process may contribute to immune bias in some stages of autoimmune disease.

The evidence so far appears simple and clear, demonstrating that in autoimmune processes the prolonged expression of iNOS is deleterious (as schematically shown in Fig. 8). However, investigations of mice lacking a functional iNOS gene have not confirmed the disease-propagating activity of this enzyme as essential for development of clinically overt illnesses, indicating that NO may just add to destruction or in some diseases, such as like autoimmune encephalitis, even

protect from cell death, as will be outlined in the following section.

Local NO Synthesis May Also Protect from Cell Death

Apoptosis is an event essential for normal development as well as physiological cell turnover. Both excess apoptosis and a failure to undergo apoptosis will result in pathological disorders. Apoptosis, or programmed cell death, is a cascade of specific biochemical and structural events (Fig. 8) that finally lead to orderly packaged cell pieces, ready to be swallowed by neighboring cells or phagocytes. Thus pathway and morphology are distinct from lytic or necrotic cell death. The morphological changes characteristic for cells undergoing apoptosis are most easily recognizable by condensation of the nucleus followed by nuclear fragmentation (Fig. 9).

Although NO is a known cytotoxic effector molecule, as outlined in the previous section, it is evident that in certain cell types endogenously produced or exogenously added NO can act protectively against apoptosis induced by different stimuli (Fig. 10). Studies on the antiapoptotic mechanisms of NO have identified a series of interactions with the ever-growing list of molecular events in the apoptotic machinery.

One of the very first steps in the apoptosis cascade appears to be the release of cytochrome *c* from mitochondria into the cytoplasm, followed by activation of proteolytic enzymes belonging to the caspase family. These are all

Figure 7 (A) Injection of a mouse with bacterial endotoxin will lead to expression of iNOS protein in the thymus within 18 hours. (B) Detection of DNA strand breaks as revealed by brown staining shows induction of apoptosis in many thymocytes located near the iNOS-positive areas. See color insert.

Cell death following NO exposure

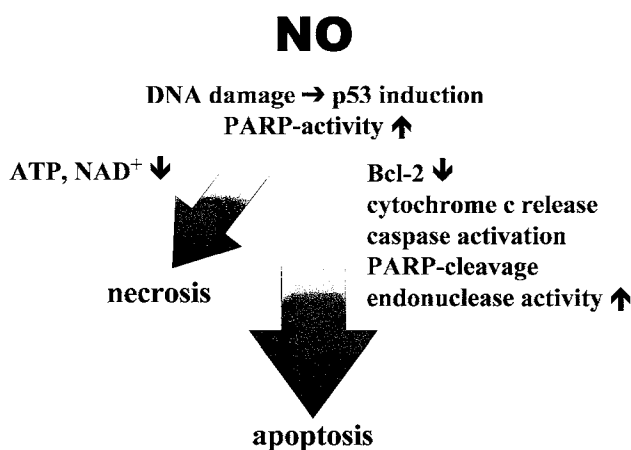

Figure 8 NO may induce apoptosis or necrosis. For instance, NO can induce DNA damage leading to simultaneous activation of poly(ADP-ribose) polymerase (PARP) and induction of p53. At this stage the cell will check whether repair is possible or whether the damage is beyond repair. In some cells activation of PARP may lead to severe depletion of NAD⁺ and ATP, and subsequently necrosis will occur. However, if the damage is beyond repair, the cell death program (apoptosis) is activated, leading to degradation of Bcl-2, release of cytochrome *c* from mitochondria, cleavage and thus inactivation of PARP, and activation of endonucleases. Whether a cell dies by necrosis or apoptosis largely depends on the cell type and the NO concentration.

Figure 9 Shown are the main characteristics of apoptotic cell death. (A) The earliest change to be seen with appropriate nuclear staining is condensation of the nuclear chromatin. (B) This will then commence to fragmentation into smaller nuclear pieces. (C) Around this time the cell membrane begins to form sacs (blebs). (D) Finally, the cell breaks up into pieces still surrounded by a membrane.

present as proenzyme forms that require proteolytic cleavage for activation. Caspases will propagate the apoptotic cascade of events by cleaving/activating other caspases, some of which will execute the terminal events in apoptosis by cleaving various substrates. For example, caspase-9

Figure 10 Some factors that may induce apoptosis in various cell types.

Protection from apoptosis as an alternate effect of NO

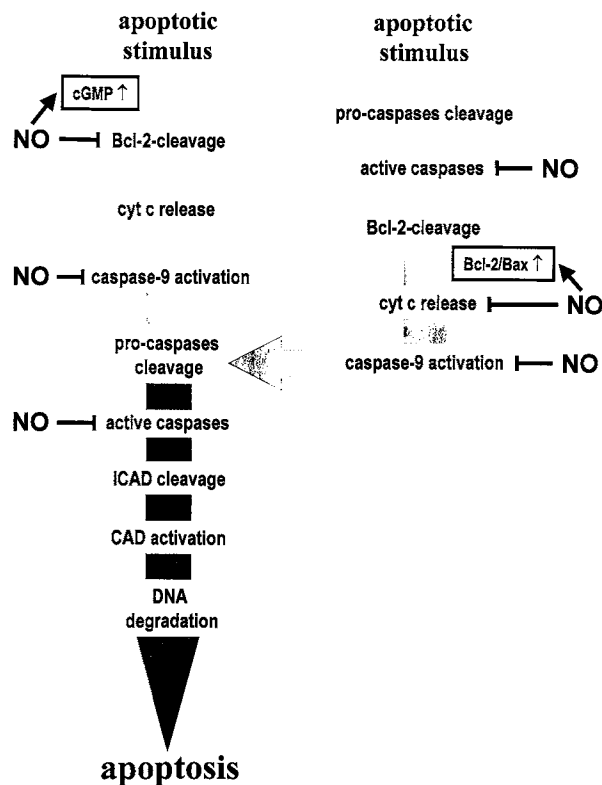

Figure 11 NO suppresses apoptosis by different mechanisms. Via activation of soluble guanylate cyclase, NO increases cGMP levels, which may inhibit signal transduction pathways early in apoptosis induction. NO may also directly inhibit caspase activation as well as inhibit caspase enzyme activities by S-nitrosylation. This results in preventing degradation of proteins of the Bcl-2 family and thus inhibits release of cytochrome *c* (cyt *c*) from mitochondria. Additionally, NO inhibits cytochrome *c* release by increasing the Bcl-2/Bax ratio. This prevents activation of downstream caspases and the terminal events in apoptosis such as the activation of caspase-activated DNase (CAD) and the cleavage of its inhibitor (ICAD).

cleaves and thereby activates caspase-3, and caspase-3 cleaves cytoplasmic and nuclear proteins, among which are fodrin and lamin, poly(ADP-ribose) polymerase (PARP), DNA-dependent kinases, and the inhibitor of the caspase-dependent activated deoxyribonuclease (ICAD) (Fig. 11).

Thus, cytochrome *c* release from mitochondria is a key event in the activation of caspases, and this step is under control of proteins in the Bcl-2 family that regulate apoptosis either positively (e.g., by Bax) or negatively (e.g., by Bcl-2). Both Bax and Bcl-2 are found in the outer mitochondrial membrane, but also in the endoplasmic reticulum and the nuclear envelope. Bax and related proteins form channels in lipid membranes and thus facilitate the leakage of cytochrome *c* from the mitochondrial outer compartment into the cytosol. In contrast, Bcl-2 and related proteins inhibit the Bax channel-forming activity, thus preventing the release of cytochrome *c* (Fig. 12).

Figure 12 Role of Bax and Bcl-2 in apoptosis. Cytochrome *c* (cyt *c*) release from mitochondria is thought to represent a key event in the activation of caspases and thus in the onset of apoptosis. Proteins of the Bcl-2 family contribute to regulation of cyt *c* release. Overexpression of Bax facilitates leakage of cyt *c*, whereas Bcl-2 forms complexes with Bax, thus preventing the release of cyt *c*. Once in the cytoplasm, cyt *c* will activate apoptotic protease activating factor-1 (Apaf-1), which will then activate caspase-9.

This life–death rheostat is influenced by NO as it regulates the gene expression of Bcl-2. For instance, we found that not only endogenous NO synthesis but also exogenously applied NO fully protects against ultraviolet A (UVA)-induced apoptosis in the skin by inducing a strong increase in Bcl-2 protein expression and inhibition of UVA-induced increases in Bax expression (Fig. 11).

Although several endogenous inhibitors of caspase activation and activity have been described, none has been shown to be more prevalent than NO. NO activates guanylate cyclase, which generates cGMP from GTP. Increased cGMP levels decrease the intracellular free Ca^{2+} concentration. High Ca^{2+} concentrations, being another key signal of apoptosis and NO/cGMP inhibition of apoptosis, involve the cGMP-dependent inhibition of caspase activation. Furthermore, all caspase proteases contain a single cysteine at the enzyme catalytic site essential for enzyme activity, and this thiol is susceptible to NO-mediated redox modification, leading to caspase inhibition. Additionally, as Bcl-2 itself is a substrate for caspase-3, NO can thus inhibit Bcl-2 cleavage and subsequent cytochrome *c* release.

Moreover, by its capacity to alter gene expression, NO will induce the expression of protective proteins such as heat-shock proteins, metallothionein, or superoxide dismutase, all of which will add to protection from apoptotic cell death. Finally, protection from both apoptosis and necrosis is found as a result of NO-mediated quenching of reactive oxygen intermediates and inhibition of lipid peroxidation. These very direct effects will suppress not only apoptotic signal transduction, but also toxic plasma membrane damage as the initial event in necrotic cell lysis (Fig. 13).

The decision for a cell to undergo apoptosis is the result of a shift in the balance between the antiapoptotic and pro-

apoptotic forces within the cell, and physiologically relevant levels of NO contribute to this balance.

NO Will Alter Cellular Gene Expression

The intricate task of regulating gene expression in the many differentiated cell types of multicellular organisms is

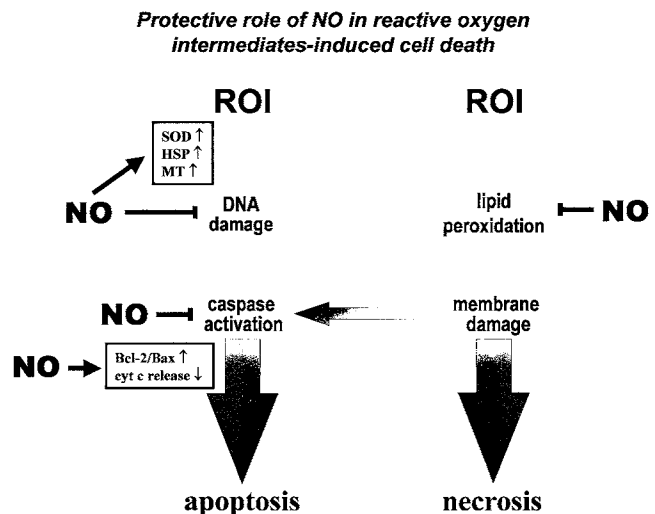

Figure 13 NO may protect from reactive oxygen intermediate (ROI)-induced apoptosis or necrosis. NO-mediated protection may occur via induction of protective proteins such as superoxide dismutase (SOD), heat-shock proteins (HSP), or metallothionein (MT), but it may also occur via direct quenching of ROIs or via inhibition of lipid peroxidation. This may lead to suppression of signal transduction pathways leading to apoptosis or to inhibition of plasma membrane damage, an initial event of necrosis.

Figure 14 The pathway of signal transduction from the initial signal to cellular protein synthesis. A signal molecule may bind to a receptor in the cell membrane, and this initial event will lead to a signal transduction and activation of transcription factors in the cytoplasm. Alternatively, signal molecules may enter the cell and directly activate signal transduction pathways or transcription factors. These activated transcription factors now enter the nucleus and specifically bind to promoter or enhancer regions of the genome. This leads to specific transcription of genes into messenger RNA, which then leaves the nucleus and will be translated into protein.

accomplished primarily by the combined actions of multiple different transcription factors, which are specific proteins required for RNA polymerase II to initiate transcription. These

transcription factors contain two domains, one that specifically binds to DNA and another that activates transcription by interacting with other components of the transcriptional machinery (transactivating domain). To induce cells to synthesize new proteins, signals from the surroundings must meet the target cell and must bind to specific receptors expressed at the cell surface, inducing several signal transduction pathways, which leads to activation of transcription factors. Alternatively, signals may also directly activate signal transduction pathways or transcription factors. After activation, transcription factors enter the nucleus and bind to specific DNA sequences in the promoter region of individual genes. This results in the formation of an initiation complex that binds and activates RNA polymerase II. The gene is then transcribed into messenger RNA, which leaves the nucleus and subsequently is translated into protein on the ribosomes (Fig. 14).

High-output NO (“nitrosative stress”) will lead to altered gene expression. NO reacts with selected molecular targets within a cell only, these are the heme group, free thiols, iron–sulfur (Fe–S) clusters, and zinc–sulfur (Zn–S) clusters. Whereas Fe–S clusters in proteins serve mostly as catalytic centers, Zn–S clusters are structural elements that provide a specific protein conformation essential for specific binding to DNA, RNA, or other proteins. Transcription factors bind to DNA via various DNA binding domains, for example, via zinc fingers, helix–turn–helix or helix–loop–helix motifs, or leucine zippers. Zinc fingers are by far the most prevalent motif and contain repeats of cysteine and/or histidine residues that bind Zn^{2+} , thereby folding looped structures in proteins. These loops often contain the DNA binding domain. NO will temporarily destroy such a structure via S-nitrosylation and subsequent ejection of Zn^{2+} , as outlined in Fig. 15. Zinc finger-dependent gene transcription will thus be inhibited by NO (Fig. 16A). However, NO will not irreversibly destroy zinc finger proteins, since the zinc finger structures can be restored by cellular redox systems, if the

Figure 15 Destruction of zinc finger structures by NO. The most prevalent DNA binding motif of proteins are so-called zinc fingers, where a Zn^{2+} ion determines a special protein conformation necessary for specific binding to DNA, RNA, or proteins. Under aerobic conditions, NO leads to S-nitrosylation and subsequent ejection of the Zn^{2+} , and this destroys the zinc finger structure and thus the DNA binding domain.

NO may inhibit or induce transcription

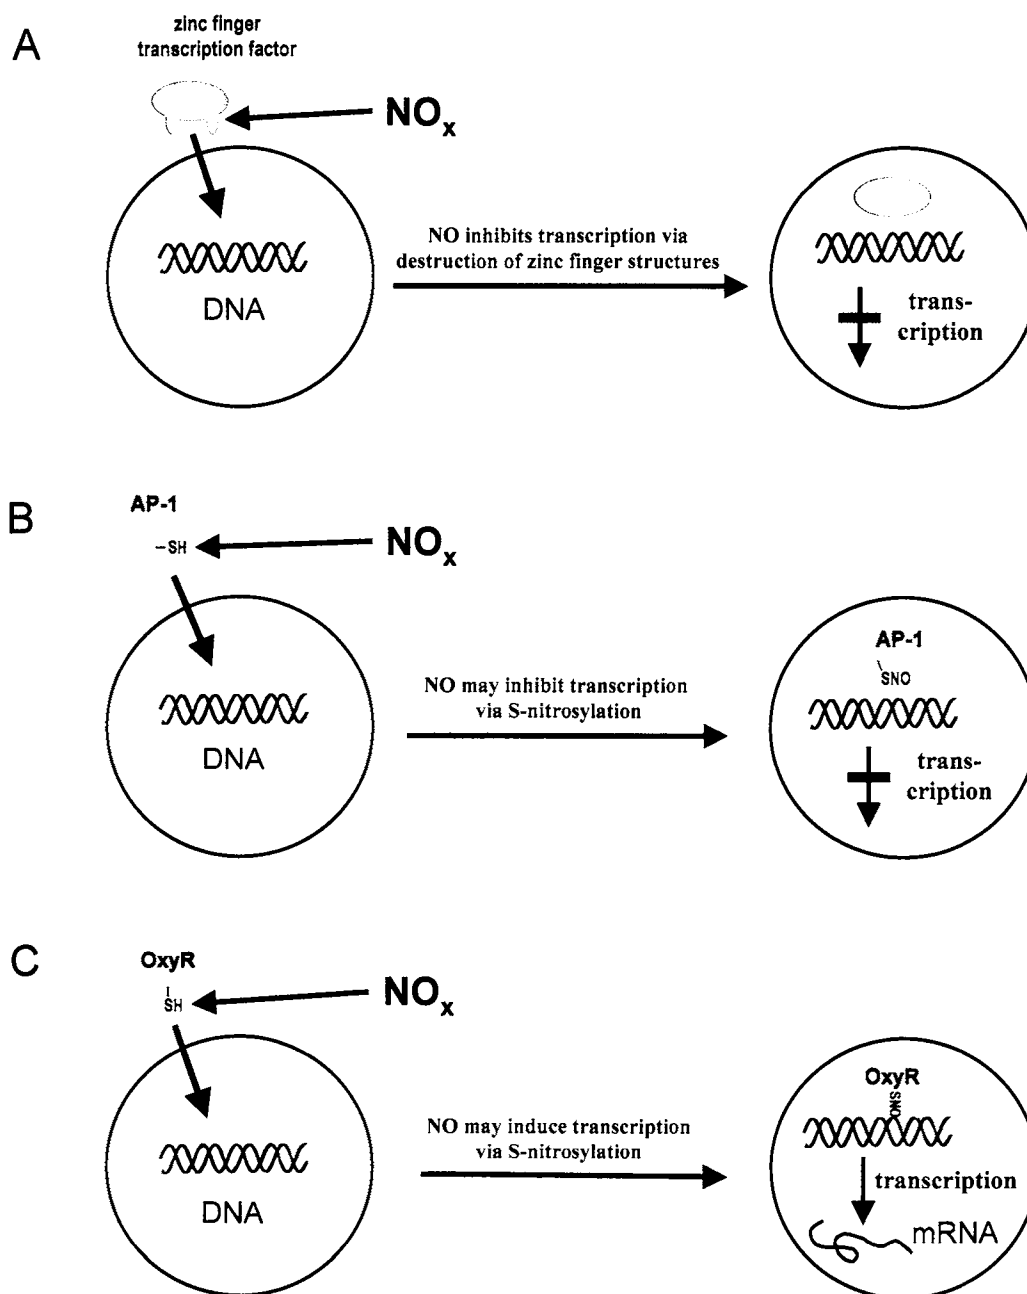

Figure 16 Inhibition or induction of transcription by NO. (A) Destruction of zinc finger structures by NO leads to inhibition of the DNA binding activity of the respective transcription factor and thus transcription. (B) The same holds true for other redox-sensitive transcription factors such as AP-1, where a cysteine residue within the DNA binding domain can be S-nitrosylated by NO, which will also result in inhibition of DNA binding. (C) However, NO may also activate transcription factors, for example, the bacterial stress sensor OxyR. In this case, S-nitrosylation leads to a conformational change in the protein that induces DNA binding of OxyR and subsequent transcription.

individual redox capacity of the cell is not overtaxed. Restoring zinc finger structures after nitrosative stress may allow a more finely tuned and specific regulatory action of NO. Importantly, once zinc finger transcription factors have bound to responsive DNA elements, they are much more

resistant toward NO, suggesting that NO inhibits transcription during its initiation only.

Besides zinc finger transcription factors, NO also inhibits the DNA binding activity of redox-sensitive non-zinc finger transcription factors such as nuclear factor κ B (NF- κ B) and

activator protein 1 (AP-1) (Fig. 16B), which both contain a cysteine residue within or close to the DNA binding domain. However, transcription factors with zinc fingers are probably the most sensitive targets. In contrast, transcription factors that lack cysteine residues essential for DNA binding or transactivating activity will not be inhibited by NO. This means that nitrosative stress unspecifically but nevertheless selectively inhibits the DNA binding activity of redox-sensitive transcription factors and thus leads to inhibition or reduction of gene expression.

In contrast, NO may also enhance transcription by reacting with other transcription factors. An example is the transcription factor OxyR, a bacterial redox-stress sensor capable of recognizing both oxidative and nitrosative stress and inducing transcription of genes for protective enzymes such as catalase or glutathione reductase. OxyR contains a critical cysteine residue, and S-nitrosylation of this cysteine activates OxyR, thus leading to specific transcription of genes (Fig. 16C). Transcriptional regulation of OxyR by S-nitrosylation thus serves as a switch to regulate gene expression of bacteria under nitrosative stress.

These few examples show that NO may regulate gene expression in either a positive or a negative direction depending on the transcription factors involved.

Conclusions

In this chapter we have listed a number of apparent contrasting ways in which NO will act on its production and release by the iNOS in tissues or cells. We have shown that NO induces apoptosis but also may kill cells via necrosis. On the other hand, we have presented evidence showing that NO will very efficiently protect cells from apoptosis and necrosis. Now, what are we going to predict, if we know of iNOS expression in a certain disease? And this is exactly the problem: We are currently not able to predict anything. Dis-

ease outcome appears to depend on the amount of NO released within a given period of time, and it also appears to depend on the exact timing of iNOS-produced NO. As an example, we have found that in human skin keratinocytes will become iNOS positive on ultraviolet irradiation. This is apparently a normal response, as healthy volunteers all show this reaction, which is detectable at the first day and lasts for another day or two. In contrast to this normal response, patients with an immune-mediated disease triggered by ultraviolet light (cutaneous lupus erythematosus) show no iNOS staining within the first 2 days and will belatedly express this enzyme from day 3 on for up to 25 days or more, which is the period during which these patients develop the characteristic skin lesions. This tells us that iNOS expression may not be much of a disease marker (as suggested in Table 1); rather, it is the inappropriate timing of its expression that is disease related. As NO can regulate gene expression in cells, this may explain why the timing of NO formation is crucial.

Another factor, which we can rarely determine in ongoing diseases, is the amount of NO locally released. There is increasing evidence for the relative concentration of NO being crucial for the outcome, with various levels of NO resulting in protection, in induction of apoptosis, or in direct necrotic effects. Moreover, these concentration ranges will be different for different cell types, as already mentioned.

PLATELETS ARE ANUCLEATE BLOOD ELEMENTS THAT PLAY A CRUCIAL ROLE IN VASCULAR HEMOSTASIS. PLATELETS ADHERE TO THE SITE OF VASCULAR INJURY, AGGREGATE, AND SEAL THE RENT IN THE VASCULAR WALL. PLATELET FUNCTION IS REGULATED VIA THE RECIPROCAL INTERACTIONS BETWEEN AGENTS THAT STIMULATE AND INHIBIT PLATELET ACTIVATION. NITRIC OXIDE (NO) IS AN IMPORTANT CONTRIBUTOR TO THE PLATELET INHIBITORY REACTIONS. NITRIC OXIDE, WHEN GENERATED BY PLATELETS AND THE ENDOTHELIUM, INHIBITS ADHESION, INHIBITS AGGREGATION, AND HELPS TO MAINTAIN VASCULAR INTEGRITY, ACTING MOSTLY THROUGH A cGMP-DEPENDENT STIMULATION OF PROTEIN PHOSPHORYLATION. VASCULAR PATHOLOGY IS OFTEN ASSOCIATED WITH ABERRATIONS OF NO GENERATION, METABOLISM, AND ACTION. RESTORATION OF THE DISTURBED BALANCE BETWEEN PLATELET MEDIATORS AND THE DEVELOPMENT OF PLATELET-SELECTIVE NO DONOR AGENTS MAY BE USED TO TREAT VASCULAR PATHOLOGIES ASSOCIATED WITH PLATELET DYSFUNCTION.

Introduction

Vascular hemostasis is a physiological process aimed at preservation of both blood fluidity and vascular integrity. The fluid state of flowing blood must be carefully balanced against another important homeostatic property of blood that is meant to protect the vascular system from the loss of fluid due to an accidental breach of vascular integrity. These diverse yet coordinated reactions form the cornerstone of physiological hemostasis. Thrombosis is a pathological extension of hemostasis that occurs when the regulatory mechanisms of physiological hemostasis are inadequate (Radomski and Radomski, 1999).

Stages of Hemostasis

When a blood vessel is injured the first discernible effect resulting from damage is the recruitment of platelets to the site of injury. This recruitment results in formation of a primary hemostatic plug, often referred to by earlier scholars as

“white aggregate.” The effectiveness of this primary vascular wall-sealing device depends on its reinforcement with a wirelike network of the strong protein fibrin, which is the final product of the protein coagulation cascade promoted by platelets. The fibrin-rich “red aggregate” is subsequently remodeled by the action of the blood fibrinolytic system, leading to vessel wall repair processes and a return to the physiological status (Fig. 1). The complexity of hemostatic reactions requires flawless performance of the regulatory checkpoints that operate at various levels of hemostasis. A failure of hemostasis in maintaining self-control may lead to thrombosis.

Blood Platelets

MORPHOLOGY AND FUNCTION

Platelets are small (~2 μm in diameter), anucleate cell fragments first described by Italian researcher Bizozzero at the end of the nineteenth century. Platelets are generated following fragmentation of the cytoplasm of large progenitor

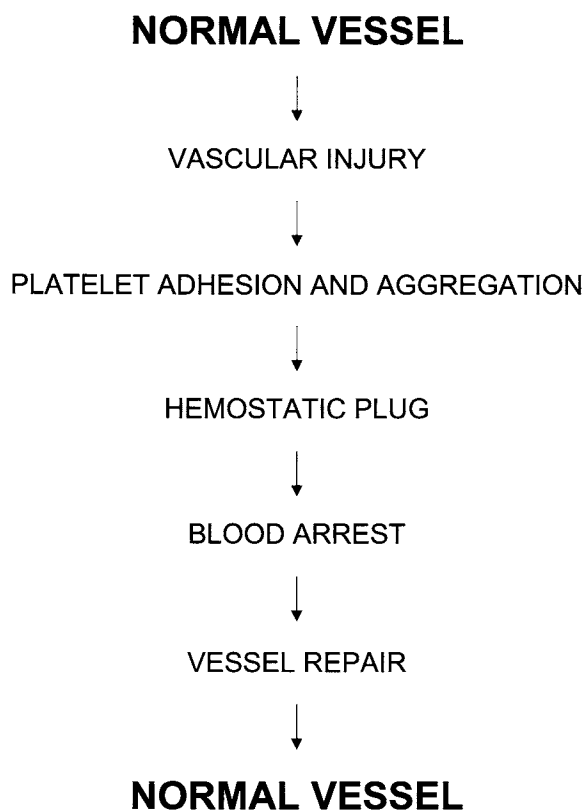

Figure 1 The main stages of vascular hemostasis.

cells, the megakaryocytes. Fragmentation of one megakaryocyte results in formation of a few thousand platelets.

Gross features of platelets can be observed using phase-contrast microscopy *ex vivo* (Fig. 2); however, closer scrutiny requires the use of electron microscopy (Fig. 3). The most striking ultrastructural features are the lack of nucleus (hence, by classic definition, platelets should be considered as cell fragments rather than cells) and the presence of numerous granules (Read *et al.*, 1985). Platelet granules contain various proactivator and mitogenic agents, including adenine nucleotides, calcium, protein growth factors, and fibrinogen.

As described earlier, vessel wall injury leads to a chain of platelet reactions. It is convenient to separate platelet reactions into three major components: adhesion, that is, the ability of a platelet to attach to a natural or foreign surface; aggregation, the ability of platelets to attach to each other; and platelet procoagulant activity, the ability to accelerate fibrin meshwork formation (Coller, 1992; Salas *et al.*, 1997a).

It is important to realize that *in vivo* platelet reactions take place in flowing blood. Blood flow determines the fundamental parameters of platelet behavior. The rheological (spatial) configuration of blood elements inside the vessel depends on the shear rate, that is, the forces generated as a result of pulsatile propulsion of blood by the working heart in the biological tubes. Red blood cells, more numerous and larger than platelets, occupy the central axial position in the vessel, forcing platelets to stream toward the endothelial lin-

ing (Radomski and Radomski, 1999). Thus, under physiological conditions platelets are in the proximal vicinity of the endothelial cells (Fig. 4). This arrangement is particularly apparent under conditions of laminar flow best seen in the microvasculature. In contrast, a turbulent flow, as detected at vessel branching or in pathological derangement of vasculature, changes this natural configuration of blood elements and facilitates thrombosis.

Platelet adhesion takes place when platelets attach and spread (similar to an egg on a frying pan) on natural surfaces (the vessel wall constituents) and on foreign surfaces (e.g., blood bank containers and the extracorporeal circuits). The platelet-surface interactions are mediated via the expression of platelet receptors (Table I). These are adhesive glycoproteins that act in gluing platelets to their stratum.

Platelet aggregation results from formation of bridges between the adjacent platelets. This process depends mainly on the expression of glycoprotein integrin IIb/IIIa by platelets, and this receptor binds fibrinogen and other plasma ligands to form the aggregate. The process of activation (a change from the low- to high-affinity conformation) of the IIb/IIIa receptor is paramount for platelet aggregation to occur. Platelet aggregation triggers structural changes in the surface membrane organization, exposing to the lumen of the vessel a highly procoagulant lipid surface that facilitates thrombin activation and fibrin formation (Coller, 1992).

Platelet aggregation is conveniently studied *in vitro* using aggregometry (Fig. 5). Both the theory and practice of platelet aggregation studies and their application to NO research were reviewed by Radomski *et al.* (1996).

PATHWAYS OF PLATELET REGULATION

Activator Reactions Research over the past 40 years has provided the biochemical rationale for these dramatic alterations in basal behavior of platelets. It is now well established that the formation of a platelet plug is supported by the activity of at least three platelet-derived activator systems.

The release of adenosine diphosphate (ADP) from platelet granules and the interactions of ADP with purinergic receptors form the foundation of the first system. *In vivo*, a platelet-derived pool of ADP may be supplemented with ADP released from red blood cells (Radomski and Radomski, 1999).

The discovery of the mechanism of action of aspirin and its congeners by Sir J. Vane (1971) formed the foundations for the discovery of the proaggregating metabolites of arachidonic acid in platelets, namely, cyclic endoperoxides and thromboxane A₂ (Hamberg *et al.*, 1974). Thromboxane A₂ is synthesized by the sequential action of platelet cyclooxygenase and thromboxane synthase, and once formed, it acts on its receptors to amplify aggregation (Moncada, 1982).

Inhibition of the generation of and the action of ADP (e.g., by ticlopidine) and thromboxane (e.g., by aspirin) is not sufficient per se to abolish platelet aggregation stimulated by such potent agonists as thrombin. In 1997, we discovered that human platelets express matrix metalloproteinase-2 (MMP-2) that, when released, stimulates platelet aggrega-

Figure 2 Phase-contrast microscopy examination of reactions of human washed platelets. (A) Resting platelets. (B) Platelet aggregate resulting from stimulation of platelets with collagen (10 $\mu\text{g/ml}$). tion in a nonthromboxane-, non-ADP-dependent manner (Sawicki *et al.*, 1997) (Fig. 6).

Inhibitor Reactions The vascular endothelium is a major contributor to the inhibitor reactions that control platelet activation.

Vane and associates first discovered that endothelial cells generate prostacyclin, a potent inhibitor of platelet aggregation and stimulator of platelet disaggregation (Moncada *et al.*, 1976). Prostacyclin is a biological opponent of thromboxane A_2 on platelets (Fig. 7) and the vessel wall resulting in inhibition of platelet aggregation and vasodilation (Moncada, 1982). Prostacyclin binds to its specific receptors present on platelets that are linked to the adenylyl cyclase. Stimulation of prostacyclin receptor leads to increased accumulation of the intracellular cAMP and downregulation of all pathways involved in amplification of platelet aggregation (Moncada, 1982). Prostacyclin exerts little influence on the process of platelet adhesion to the subendothelial components of the vessel wall (Radomski *et al.*, 1987a,b).

Prostacyclin acts as a paracrine inhibitor of platelet activation. It is released close to the endothelial surface in response to stimulation with various vasoactive mediators including angiotensins and bradykinin (Nowak *et al.*, 1981).

Platelets themselves lack the capacity to synthesize prostacyclin; however, they may contribute to the endothelial synthesis of this eicosanoid by generating and releasing arachidonic acid cyclic endoperoxides, which may be taken up by the endothelial cells for prostacyclin synthesis (Moncada, 1982).

Some of lipoxygenase metabolites of polyunsaturated fatty acids, including 12-hydroperoxy and 13-hydroxy derivatives of arachidonic and linoleic acids, respectively, have been shown to inhibit the process of platelet activation (Aharony *et al.*, 1981; Buchanan and Brister, 1991). The precise mode of action of these metabolites on platelets is not known.

Nitric Oxide

Search for Noneicosanoid Regulators of Platelet Function

The discovery of prostacyclin, a major platelet-regulatory prostaglandin, intensified research aimed at understanding the mechanisms of platelet regulation. Indeed, it soon became apparent that the generation and release of this eicosanoid

Figure 3 Ultrastructural features of human platelets. (A) Low-power (20,000 \times) examination of resting platelets. Physiologically, the shape of resting platelets is discoid (1). Platelets in the aggregate show various degree of degranulation.

can only account in part for nonthrombogenic properties of vascular endothelium. The endothelial cells can express the antiaggregatory activity even under conditions of complete inhibition of prostaglandin generation (Radomski *et al.*, 1987c,d).

The discovery of endothelium-dependent relaxation (Furchgott and Zawadzki, 1980) and the fact that endothelium-derived relaxing factor (EDRF) appeared not to be a metabolite of arachidonic acid has added new impetus to this search. The study of Azuma and colleagues (1986) suggested that EDRF might be acting as an inhibitor of platelet aggregation. In 1986–1987, we investigated noneicosanoid, platelet-inhibitory properties of endothelial cells and found that these could be accounted for by the release of EDRF. Moreover, the pharmacological properties of EDRF were identical with those of nitric oxide (NO) gas on platelets.

Furthermore, the measurement of NO released during platelet regulation by the endothelium showed that its generation could account for the platelet-inhibitory activities of EDRF on platelet adhesion and aggregation (Radomski *et al.*, 1987a–d). Interestingly, the endogenous NO proved to be identical in its antiplatelet spectrum with that generated during cigarette smoking and by pharmacologically related vasodilators, as demonstrated by Ignarro and co-workers (Mellion *et al.*, 1981).

The description of the L-arginine to NO pathway in endothelial cells (Palmer *et al.*, 1988) stimulated the search for the presence of nitric oxide synthase (NOS) in platelets. The rationale for this research was provided by previous observations that platelet activation was associated with increased generation of cyclic guanosine 3',5'-monophosphate (cGMP) (Goldberg *et al.*, 1975) and by the experiments of Ignarro

Figure 4 The arrangement of platelets in blood under the conditions of laminar flow.

and colleagues showing that NO gas inhibited aggregation in a cGMP-dependent manner (Mellion *et al.*, 1981). In 1990–1993, we provided biochemical and pharmacological characteristics of platelet NOS (Radomski *et al.*, 1990a,b), and we measured the activity of the enzyme during platelet stimulation using a selective porphyrinic microsensor (Malinski *et al.*, 1993). More recently, a number of groups reported the molecular characteristics of platelet NOS (Muruganandam and Mutus, 1994; Chen and Mehta, 1996; Wallerath *et al.*, 1997; Berkels *et al.*, 1997).

Molecular Biology of NO Generation by Platelets

In contrast to megakaryocytes, which contain large amounts of RNA and DNA, platelets contain trace amounts of DNA and small amounts of RNA. Therefore, the identification of

DNA fragments coding NOS proteins requires application of reverse transcriptase-polymerase chain reaction (RT-PCR). A number of researchers extracted platelet RNA and amplified DNA fragments consistent with expression of endothelial NOS (eNOS) but not inducible NOS (iNOS) or neuronal NOS (nNOS) in platelets (Sase and Michel, 1995; Mehta *et al.*, 1995; Wallerath *et al.*, 1997).

Although the presence of eNOS mRNA in normal platelets (Sase and Michel, 1995; Mehta *et al.*, 1995) appears to be beyond dispute, the identification of iNOS mRNA has proved to be controversial. Chen and Mehta (1996) but not Wallerath and colleagues (1997) found mRNA for iNOS in normal platelets. It is possible that a short half-life iNOS

mRNA (6 hours) (Geng and Lotz, 1995) accounts for this discrepancy.

Muruganandam and Mutus (1994) first purified to homogeneity platelet NOS protein. The isolated protein was cytosolic, and the molecular mass of the monomer was found to be approximately 80 kDa. Western blot, immunocytochemistry, and NADPH diaphorase staining have been used to study NOS protein isoforms in platelets. The immunological methods detected the presence of eNOS and iNOS immunoreactivity in normal human and porcine platelets (Chen and Mehta 1996; Wallerath *et al.*, 1997; Berkels *et al.*, 1997). In contrast to the studies by Muruganandam and Mutus (1994) and Mehta *et al.* (1995), other researchers found platelet eNOS, similar to endothelial eNOS, to be associated with the particulate fraction of the platelet (Wallerath *et al.*, 1997; Berkels *et al.*, 1997). It is possible that platelet eNOS undergoes intracellular translocation and activation during platelet activation (Radomski *et al.*, 1990a,b; Berkels *et al.*, 1997).

The significance of iNOS protein expression under physiological conditions in platelets remains to be elucidated. Platelets have a limited capacity to synthesize protein *de novo*, and they acquire most of their proteins from megakaryocytes. We and others have shown that cytokine-stimulated megakaryoblasts and bone marrow megakaryocytes express iNOS (Lelchuk *et al.*, 1992; Wallerath *et al.*, 1997). Megakaryocytopoiesis (growth and differentiation of megakaryocytes) and thrombopoiesis (platelet formation following megakaryocyte fragmentation) are physiological processes that are cytokine dependent and regulated by the stimulatory and inhibitory cytokines (Brown and Martin, 1994). It is possible that the changes in expression of iNOS in platelets occur physiologically as a result of interactions between factors controlling thrombopoiesis and megakaryocytopoiesis.

Factors Regulating NO Generation in Vascular Hemostasis

Nitric oxide available for platelet regulation is generated by both endothelium- and platelet-derived NOS (Fig. 8). Stimulation of platelet and endothelial function plays an important role in the generation of NO. Tonic release of NO from the endothelial cells is likely to be mediated by shear stress (Busse and Fleming, 1998). Resting platelets generate small amounts of NO (Zhou *et al.*, 1995; Malinski *et al.*, 1993). Platelet adhesion and aggregation stimulate platelet NOS, leading to the release of NO (Polanowska-Grabowska and Gear, 1994; Radomski *et al.*, 1990a; Malinski *et al.*, 1993; Lantoiné *et al.*, 1995).

The substrate for NOS, L-arginine, is present in high concentrations in plasma and the intracellular compartment. These concentrations are many times higher than K_m for NOS, suggesting that under resting conditions L-arginine may not be a rate-limiting factor for NO generation. In contrast, endothelial and platelet activation lead to stimulation of NOS and generation of substantial amounts of NO (Radomski *et al.*, 1990a; Bode-Boger *et al.*, 1998).

Platelet- and endothelium-derived eNOS are NADPH, bipterin, and flavin dependent (Salas *et al.*, 1997a; Berkels *et al.*, 1997). The availability of calcium appears to be crucial for the activity of eNOS, as its removal abolishes the enzyme activity (Radomski *et al.*, 1990a). Interestingly, there is an apparent lack of correlation between changes in the intraplatelet calcium levels and activation of platelet-

Figure 8 Generation and physiological effects of NO in the platelet–endothelium microenvironment. + denotes stimulation; – denotes inhibition.

derived eNOS (Malinski *et al.*, 1993; Lantoiné *et al.*, 1995). The reasons for this discrepancy are unclear.

As explained in earlier, the rheological conditions, that is, the positioning of platelets against the vascular wall in flowing blood, exert strong influence on platelet function. Indeed, the placement of platelets in the proximal vicinity of the endothelial lining facilitates regulation of platelet function by the endothelium-derived NO (Radomski and Radomski, 1999). Moreover, red blood cells containing hemoglobin, a NO scavenger, stream toward the axial part of the vascular lumen.

Physiological Regulation of Platelet Function by NO

Early experiments examined the effects of NO on platelet adhesion and aggregation *in vitro*. Both basal (shear stress-dependent) and agonist-stimulated release of NO have been implicated in platelet regulation. Indeed, the coronary and pulmonary vasculatures generate NO to inhibit platelet adhesion under constant flow conditions (Venturini *et al.*, 1989; Pohl and Busse, 1989). Similarly, bradykinin-stimulated endothelial cells release NO in quantities sufficient to inhibit platelet adhesion (Radomski *et al.*, 1987b,c; Sneddon and Vane, 1988).

Platelet aggregation induced by a variety of agonists, as well as by shear stress, is inhibited by NO released from fresh or cultured endothelial cells (Radomski *et al.*, 1987c,d; Furlong *et al.*, 1987; Busse *et al.*, 1987; Macdonald *et al.*, 1988; Alheid *et al.*, 1989; Houston *et al.*, 1990; Broekman *et al.*, 1991). In addition to inhibition of adhesion and aggregation, NO disaggregates preformed platelet aggregates (Radomski *et al.*, 1987d) and inhibits platelet recruitment to the aggregate (Freedman *et al.*, 1997).

There is now convincing evidence that NO is an important regulator of platelet function *in vivo*. Animal studies have shown that basal or stimulated release of NO results in inhibition of platelet aggregation induced by some aggregating agents or endothelial injury (Rosenblum *et al.*, 1987; Bhardwaj *et al.*, 1988; Hogan *et al.*, 1988; Humphries *et al.*, 1990; Herbaczynska-Cedro *et al.*, 1991; May *et al.*, 1991; Golino *et al.*, 1992; Yao *et al.*, 1992; Houston and Buchanan, 1994). In addition, studies in humans evidenced that there is basal luminal release of NO from the vasculature, causing increases in the intraplatelet cGMP levels (N. P. Andrews *et al.*, 1994). In healthy volunteers, inhibition of NOS with *N*^G-monomethyl-L-arginine (L-NMMA) increased platelet aggregation granule release *ex vivo* (Bodzenta-Lukaszyk *et al.*, 1994) and shortened bleeding time (Simon *et al.*, 1995). In contrast to L-NMMA, L-arginine administration *in vivo* leads to the inhibition of platelet activation *ex vivo* (Caren and Corbo, 1973; Adams *et al.*, 1995; Bode-Boger *et al.*, 1998). Both the vasodilator (Houston and Buchanan, 1994) and platelet-inhibitory (Yao *et al.*, 1992; Golino *et al.*, 1992; Bodzenta-Lukaszyk *et al.*, 1994; Adams *et al.*, 1995; Bode-Boger *et al.*, 1998) components contribute to the hemostatic action of NO.

Early studies reviewed by Radomski and Moncada (1991) showed that platelet activation and thrombus formation occur as a result of synergistic interactions between proaggregating agents. In 1987, we found that synergistic interactions also take place between agents that inhibit platelet aggregation. Indeed, the endothelial cells generate and release NO and prostacyclin that act in concert to maximize the extent of platelet inhibition and vessel wall protection (Radomski *et al.*, 1987d) (Fig. 9). Similar synergistic interactions occur between NO and other inhibitors of platelet activation (for references, see Salas *et al.*, 1997a). The biological significance of the synergistic regulation of platelet function is to ensure a multilevel control of this process and minimize the impact of pathological alterations on hemostasis.

A biological counterpart for MMP-2 (Fig. 6) has been identified in the vessel wall and in platelets (Fernandez-Patron *et al.*, 1999). This is another matrix metalloproteinase enzyme (MMP-9) (Fig. 10). The interactions between NO, prostacyclin, and MMP-2 remain to be studied.

Mechanisms of Platelet Regulation by NO

Similar to many cell and tissue systems, the effects of NO on platelets are largely dependent on the stimulation of the soluble guanylyl cyclase (GC-S) and the resultant increase in the intraplatelet cGMP levels. However, some actions of NO on platelets may also be independent of GC-S activation.

SOLUBLE GUANYLYL CYCLASE

It is now generally accepted that NO activates soluble GC-S by binding to the heme moiety of the enzyme (Craven and DeRubertis, 1978). The binding of NO to GC-S results

Figure 9 Synergistic interactions between NO and prostacyclin as inhibitors of platelet aggregation. (A) Endogenous NO and prostacyclin (PGI₂) released from cultured endothelial cells by bradykinin (Bk) maximally inhibit collagen-induced platelet aggregation *in vitro*. The NO-dependent part of this inhibition is abolished by hemoglobin (Hb), a NO scavenger. PGI₂-dependent inhibition is decreased by aspirin (ASA). (B) Synthetic NO and PGI₂ synergize as inhibitors of platelet aggregation. Graphs adapted from data in Radomski *et al.* (1987c,d).

Figure 10 Factors involved in inhibition of platelet activation.

in the conversion of magnesium guanosine 5'-triphosphate to guanosine 3',5'-monophosphate (cGMP) (Mellion *et al.*, 1981). Indeed, platelet fractions containing GC-S readily sequester NO gas (Liu *et al.*, 1993).

Three proteins mediate the actions of cGMP on platelets: cGMP-dependent protein kinase, cGMP-binding cAMP phosphodiesterase, and cGMP-regulated ion channels (Walter, 1989). Stimulation of cGMP-dependent protein kinase results in phosphorylation of proteins (Walter, 1989) such as the 46- to 50-kDa vasodilator-stimulated phosphoprotein (VASP, Haffner *et al.*, 1995). During platelet adhesion VASP is associated with actin filaments and focal contact areas, that is, transmembrane junctions between microfilaments and the extracellular matrix (Reinhard *et al.*, 1992). The binding of VASP with the platelet cytoskeleton may mediate its inhibitory effect on the fibrinogen receptor (Horstrup *et al.*, 1994). More recently, it has been shown that cGMP mediates phosphorylation of the carboxyl terminus of thromboxane receptor (Wang *et al.*, 1998). The thromboxane receptor is a G-protein-coupled receptor, and its phosphorylation by cGMP-dependent protein kinase disrupts receptor–G-protein coupling and inhibits thromboxane-mediated platelet aggregation.

Cyclic GMP may also interfere with the transport of biogenic amines into platelets. Indeed, cGMP-induced protein phosphorylation may downregulate the uptake of serotonin by platelets (Launay *et al.*, 1994).

Cyclic GMP decreases basal and stimulated concentrations of intracellular Ca^{2+} (Nakashima *et al.*, 1986; Johansson and Haynes, 1992). A number of systems that regulate Ca^{2+} trafficking have been identified in platelets. These include the receptor-operated channels, the Ca^{2+} -ATPase extrusion pump, the $\text{Na}^+/\text{Ca}^{2+}$ exchanger, the Ca^{2+} -accumulating ATPase pump of the dense tubular membrane (an intraplatelet membrane Ca^{2+} store), and passive leakage and receptor-operated Ca^{2+} channels in the dense tubular membrane. These systems could be affected by cGMP. It has been shown that cGMP increases the activity of the Ca^{2+} -ATPase extrusion pump and leakage across the plasma mem-

brane (Johansson and Haynes, 1992). In addition, cGMP causes inhibition of Ca^{2+} mobilization from intraplatelet stores, including the dense tubular membrane (Nakashima *et al.*, 1986). All these effects of cGMP lead to decreased availability of Ca^{2+} within and in the proximal vicinity of platelets.

Metabolism of membrane phospholipids may be also a target for the action of cGMP. Indeed, the inhibition of phospholipases C and A_2 has been implicated in the mechanism of this action on platelets (Nakashima *et al.*, 1986; Sane *et al.*, 1989).

Cyclic GMP downregulates the function of some platelet receptors, including the fibrinogen receptor IIb/IIIa, and it downregulates protein kinase C-induced expression of P-selectin and the release of lysosomal protein CD63 (Salas *et al.*, 1994; Murohara *et al.*, 1995; Mendelsohn *et al.*, 1990; Michelson *et al.*, 1996). Interestingly, von Willebrand and fibronectin receptors appear not to be regulated by cGMP (Michelson *et al.*, 1996; Shahbazi *et al.*, 1994).

Cyclic GMP, by inhibiting cGMP-inhibited cAMP phosphodiesterase, may delay the hydrolysis of cAMP and enhance the biological effects of the latter nucleotide (Maurice and Haslam, 1990). However, the physiological and pharmacological relevance of this “cross talk” between cAMP and cGMP pathways is unclear (Radomski *et al.*, 1992).

CYCLIC GMP-INDEPENDENT ACTION OF NO ON PLATELETS

Some authors suggested that some actions of NO on platelets might be independent of the generation of cGMP. These could be direct actions of NO on calcium flux (Menshikov *et al.*, 1993), metabolism via inhibition of ADP ribosylation (Brune and Lapetina, 1989), and inhibition of 12-lipoxygenase (Nakatsuka and Osawa, 1994).

Studies suggest that some NO donor compounds such as S-nitrosoglutathione (GSNO) may inhibit platelet function in both a cGMP-dependent and cGMP-independent manner (Gordge *et al.*, 1998). Cyclic GMP-independent actions of GSNO would involve reactions dependent on the presence of thiols and copper.

Studies attempting to investigate the role of GC-S in mediation of the physiological effects of NO on platelets have been handicapped for a long time by the lack of a potent and selective inhibitor of this enzyme. Both methylene blue and LY83583, which were widely used to inhibit GC-S, lack selectivity and interact with a number of molecular targets beside GC-S (for references, see Moro *et al.*, 1996). We characterized 1*H*-[1,2,4]oxadiazolo[4,3-*a*]quinoxalin-1-one (ODQ) as a potent and selective inhibitor of GC-S (Moro *et al.*, 1996; Martinez-Cuesta and Radomski, 1998). Using this compound we have shown that both the antiaggregation and adhesion-inhibitory effects of NO *in vitro* are sensitive to inhibition by ODQ and thus are cGMP dependent.

The biological actions of cGMP are terminated by cGMP phosphodiesterase and by its efflux from platelets, and they may also depend on the activity of protein phosphatases (Walter, 1989). An overview of effects of NO on platelets is shown in Fig. 11.

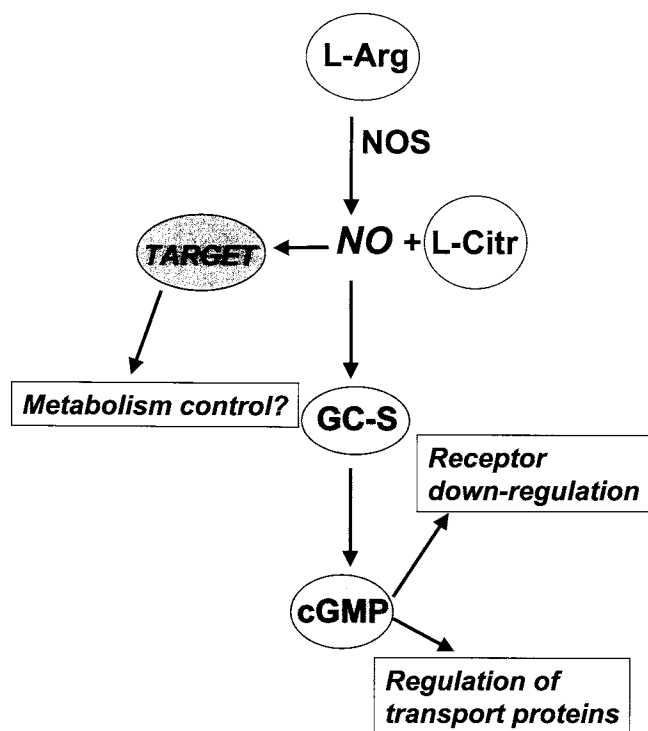

Figure 11 Cyclic GMP-dependent and -independent regulation of platelet activation.

Pathological Disruption of NO Generation and Action, and Its Involvement in the Pathogenesis of Vascular Disorders Associated with Platelet Dysfunction

The vasodilator and platelet-regulatory functions of the endothelium are impaired during the course of vascular disorders, including atherosclerosis, coronary artery disease, essential hypertension, diabetes mellitus, and preeclampsia (DeBelder and Radomski, 1994); however, the reasons underlying this impairment are not clear. The endothelial dysfunction was ascribed to both decreased and enhanced generation of NO. To explain this discrepancy it was proposed that the changes in the generation of NO are often accompanied by reduced bioactivity of NO (Radomski and Salas, 1995) (Fig. 12).

A detrimental effect of superoxide ion generation on the NO-dependent cellular signaling was first demonstrated by Gryglewski *et al.* (1986). In 1990, Beckman and associates found that superoxide reacts under conditions of physiological pH with NO to form peroxynitrite (ONOO^-) (for references, see Beckman and Tsai, 1994). Peroxynitrite is a highly reactive oxidant that can oxidize various biomolecules in the cellular microenvironment. In 1994, we found that ONOO^- can decrease the vasodilator and platelet-inhibitory activity of NO and prostacyclin (Moro *et al.*, 1994; Villa *et al.*, 1994). Thiols and glucose (Moro *et al.*, 1994, 1995) attenuated these detrimental effects of ONOO^- . The reaction of ONOO^- with thiols in cell membranes and glucose in the extracellular fluid results in the synthesis of NO donor agents

Figure 12 Some pathological factors that affect the bioactivity of NO. Ox-LDL, oxidized low-density lipoproteins; inhibitors, endogenous inhibitors of NOS including dimethylated analogs of L-arginine; HPETE, hydroperoxides of arachidonic acid.

that counteract the vasoconstrictor and platelet-aggregatory activities of the parent oxidant (Moro *et al.*, 1994; Brown *et al.*, 1998). Interestingly, there is now evidence that ONOO^- may be generated during aggregation of normal platelets (Naseem and Bruckdorfer, 1997). Indeed, tyrosine nitration, a marker of ONOO^- generation, has been detected in resting platelets. Moreover, there was increased generation of nitrated tyrosine in agonist-stimulated platelets. The nitration of tyrosine residues could influence the tyrosine phosphorylation reactions that play a paramount role in controlling platelet function.

Under physiologic conditions the impact of ONOO^- generation in the platelet microenvironment is likely to be downregulated following its reactions with platelet thiols. These reactions result in the conversion of the oxidant to NO donor agents (Brown *et al.*, 1998). The oxidizing stress could decrease the efficiency of this regulating mechanism and precipitate platelet dysfunction and damage.

ATHEROSCLEROSIS, THROMBOSIS, AND HYPERTENSION

Atherogenesis is associated with profound changes in the oxidative status of the vascular wall. Oxidative modifications of low-density lipoproteins (LDL) play a key role in atherogenesis, and a number of studies (reviewed by Radomski and Salas, 1995) have examined the effects of native and oxidized LDL on NO-mediated vascular functions. In most of these studies lipoproteins decreased the bioactivity of NO (Luscher *et al.*, 1993; Cooke and Tsao, 1992, and references therein). The decreased bioactivity of NO in atherosclerosis could also result from changes in the metabolism of this molecule and generation of ONOO^- from superoxide and inducible NO (Beckman and Tsao, 1994). In addition, LDL may inhibit L-arginine uptake into platelets and through this

mechanism decrease NOS activity and promote thrombosis (Chen and Mehta, 1994). These effects are prevented by the administration of L-arginine in the diet (Tsao *et al.*, 1994). In contrast to LDL, high-density lipoproteins (HDL) decreased platelet activation and thrombosis by increasing NOS activity in platelets (Chen and Mehta, 1994). Moreover, human apolipoprotein E, which mediates hepatic clearance of lipoproteins, exerts a significant inhibitory effect on platelets through stimulation of platelet NOS (Riddell *et al.*, 1997).

Lipid peroxidation also leads to free radical-catalyzed generation of F_2 prostaglandin isomers from peroxidation of arachidonic acid. Interestingly some of these isoprostanes, such as 8-epiprostaglandin $F_{2\alpha}$, reduce the antiadhesive and antiaggregatory activity of NO on platelets (Minuz *et al.*, 1998). Thus, lipid peroxidation contributes to the pathomechanism of impaired bioactivity of NO in the cardiovascular system.

Ischemic heart disease and myocardial infarction are common manifestations of coronary atherosclerosis. The endogenous NO inhibited microthromboembolism in the ischemic heart, protected myocardium against intracoronary thrombosis, and decreased platelet deposition owing to carotid endarterectomy (Komamura *et al.*, 1994; Olsen *et al.*, 1996). Moreover, decreased generation of NO by platelets is predictive of the presence of acute coronary syndromes in patients with coronary atherosclerosis (Freedman *et al.*, 1998). In addition, acetylcholine-induced release of NO is impaired in patients with coronary artery disease, contributing to a reduction in the endothelial capacity to regulate platelet activation (Diodati *et al.*, 1998). The data clearly show that the alterations in the generation and action of NO are important for the pathogenesis of atherogenesis and its ischemic complications.

Interestingly, an impaired NO generation or action may also underlie the pathomechanism of vasospastic and thrombotic changes of essential hypertension (Cadwgan and Benjamin, 1993; Calver *et al.*, 1992).

DIABETES MELLITUS

There are indications that changes in the bioactivity and metabolism of NO are involved in the pathogenesis of vasculopathy in diabetes mellitus. Insulin, at physiological concentrations, inhibits platelet activation via stimulation of platelet NOS (Trovati *et al.*, 1997). This suggests that a reduced generation of NO in insulin-deficient states could contribute to platelet hyperactivity and diabetic angiopathy. We have examined the formation of NO in the vasculature and platelets of JCR-LA-cp rats, which serve as a model of insulin-resistant states associated with obesity and complicated by atherosclerosis. We have found that generation of NO is crucial for the preservation of vascular homeostasis under these conditions (McKendrick *et al.*, 1998).

VASCULAR INJURY CAUSED BY STRESS

Generation of vascular NO in response to stress protects the vasculature from the vasoconstrictor and platelet-activator effects of stress hormones (Leza *et al.*, 1998). However, the

capacity of the vasculature to offset the detrimental effects of stress appears to be limited, and longer-lasting stress exposure leads to decreased generation of platelet NO, thus facilitating platelet activation and thrombosis (Leza *et al.*, 1998).

PREECLAMPSIA

Vasoconstriction and increased platelet activation are also characteristic for preeclampsia, a severe disease that may complicate normal pregnancy. We have measured the activity of NOS and GC-S in preeclamptic women and compared it with nonpregnant and healthy pregnant subjects. Paradoxically, increased generation of NO in platelets of preeclamptic women was associated with increased platelet activation (Salas *et al.*, 1997b). However, despite increased formation of NO, the activity of GC-S was reduced in preeclamptic women, suggesting that this NO was not bioactive, that is, it failed to inhibit platelet activation. We hypothesized that enhanced generation of $ONOO^-$ could contribute to platelet dysfunction and damage in preeclampsia.

ENDOTOXIN, SEPTICEMIA, AND EXPRESSION OF iNOS

The invasion of gram-negative bacteria and exposure of cells to bacterial toxins and cytokines (for references, see DeBelder and Radomski, 1994; Radomski, 1995) lead to a life-threatening syndrome often referred to as septic shock. Bacterial toxins and cytokines cause induction of a number of enzymatic systems, including NOS. It is generally accepted that stimulation of the cascade of cytokines leads to upregulation of expression of inducible enzymes, including NOS.

Cytokine-induced expression of iNOS in the vessel wall is very well documented. However, the interactions of endotoxin with platelets are controversial. Platelets have a very limited capacity to synthesize protein *de novo*. Hence, a major part of the effect of endotoxin on platelets may be indirect and may require megakaryocytic iNOS protein to be passed onto platelets (Lelchuk *et al.*, 1992). Interestingly, there is some evidence for the presence of iNOS in normal platelets. As mentioned earlier, this basal expression of iNOS in platelets may reflect the dynamism of thrombopoiesis and megakaryocytopoiesis. The presence of iNOS in normal platelets could potentially explain reports showing acute effects of endotoxin on normal platelets that were mediated via generation of NO by iNOS (Mehta *et al.*, 1995; Sheu *et al.*, 1998). These authors hypothesized that basally expressed iNOS is inactive, owing to its being complexed with a large protein carrier, and that endotoxin has a capacity to remove protein blockade and stimulate iNOS-mediated production of NO.

Considering all these data, the expression of iNOS is likely to have complex repercussions for vascular hemostasis. Inducible NO could attenuate the detrimental effects of bacterial toxins on hemostasis resulting from stimulation of the clotting cascade (disseminated intravascular coagulation). Indeed, inhibition of NO generation by NOS inhibitors potentiated cytokine-stimulated platelet adhesion to cultured human endothelial cells (Radomski *et al.*, 1993), precipitated

renal glomerular thrombosis (Schultz and Raij, 1992), and exacerbated sepsis-induced renal hypoperfusion (Spain *et al.*, 1994) *in vivo*. On the other hand, exposure of endothelial cells to cytokine-induced NO may result in cell toxicity and destruction (Palmer *et al.*, 1992), and it has been reported that inhibition of NOS may be beneficial in the treatment of septic shock (Kilbourn *et al.*, 1990; Wright *et al.*, 1992). A partial explanation for this discrepancy may be that the currently available inhibitors of iNOS are not selective and inhibit the activities of other NOS isoenzymes. Indeed, an intact generation of constitutive NO may be important in maintaining the integrity of the microvasculature during sepsis.

UREMIA

Platelet diathesis associated with bleeding is a classic complication of uremia due to the suppression of platelet function by the disease process. As early as 1970, it was found that L-arginine and some other metabolites of the urea cycle are accumulated in uremia (Horowitz *et al.*, 1970). More recent work showed that uremia leads to an increase in cytokine levels (Noris *et al.*, 1993). Platelets obtained from uremic patients generate more NO than controls, so that increased expression and/or activity of NOS may play a role in the platelet dysfunction observed in this condition.

CANCER

Platelets contribute to the cytotoxic cell effector system controlling neoplasia (for references, see Okada *et al.*, 1996). A part of this cytotoxic mechanism of platelets could be NO dependent (Okada *et al.*, 1996).

Platelets also play a role in the pathogenesis of tumor metastasis by increasing the formation of tumor cell–platelet aggregates, thus facilitating cancer cell arrest in the microvasculature. Tumor cell-induced platelet aggregation *in vitro* is modulated by the ability of tumor cells to generate NO, and this correlates with their propensity for metastasis (Radomski *et al.*, 1991). Indeed, human colon carcinoma cells isolated from metastases exhibited lower NO activity than cells isolated from the primary tumor. Moreover, the expression of iNOS by murine melanoma cells inversely correlated with their ability to form metastases *in vivo* (Dong *et al.*, 1994). These data suggest that a differential synthesis of NO may distinguish between cells of low and high metastatic potential. Interestingly, NOS has been found in some human gynecological malignancies, and the highest NOS activities were detected in poorly differentiated tumors (Thomson *et al.*, 1994). Thus, further work is needed to unravel the biological significance of NO for tumor growth, tumor metastasis, and platelet–tumor cell interactions.

Another interesting aspect of NO action on the metastatic cascade of events is its interactions with matrix metalloproteinases (MMPs). Matrix metalloproteinases represent a family of matrix-degrading enzymes that play an important role in the growth, invasion, and metastasis of cancer cells (Stetler-Stevenson, 1996). We have found that MMP-2 plays a crucial role in tumor cell-induced platelet aggregation

(Sawicki *et al.*, 1999). The release of MMP-2 was inhibited by NO donor agents, suggesting that NO may interfere with cancer invasion and spread by reducing the release of MMPs.

Pharmacology of NO Gas and NO Donor Agents on Platelets

L-ARGININE, THE SUBSTRATE FOR ENDOGENOUS GENERATION OF NO

The amounts of endogenous L-arginine in the platelet microenvironment are high (millimolar), suggesting that the availability of substrate is unlikely to constitute a rate-limiting factor for activation of platelet eNOS. Indeed, pharmacological stimulation of resting platelets with L-arginine does not result in the generation of NO (Radomski *et al.*, 1990a). Platelet activation is a potent stimulus for stimulation of NOS, and under these conditions exogenous L-arginine is promptly converted by platelet eNOS to NO (Radomski *et al.*, 1990a; Malinski *et al.*, 1993; Freedman *et al.*, 1997; Bode-Boger *et al.*, 1998). The presence of extracellular calcium is crucial for the activation of platelet eNOS by L-arginine, as the platelet-inhibitory activity of L-arginine in citrated platelet-rich plasma (low calcium levels) is lower than in whole blood anticoagulated with hirudin, which preserves physiological calcium levels (Radomski *et al.*, 1990a; Bode-Boger *et al.*, 1998).

In contrast to eNOS, basal expression of iNOS activity in vascular disorders such as atherosclerosis and preeclampsia (Dube *et al.*, 1998; Salas *et al.*, 1997b) may be sufficient to ensure the enzymatic conversion of L-arginine to NO. Indeed, Cooke and colleagues (Tsao *et al.*, 1994) provided convincing evidence for the platelet-inhibitory actions of L-arginine when administered to animals and humans with atherosclerosis. Moreover, pharmacological administration of L-arginine to patients suffering from coronary artery disease and peripheral arterial obstructive disease alleviated the symptoms of arterial insufficiency (Slawinski *et al.*, 1996; Ceremuzynski *et al.*, 1997). Thus, L-arginine may be a useful pharmacological agent in treatment of vascular disorders associated with platelet activation.

ACTIVATORS OF NOS

Some pharmacological agents inhibit platelet function via stimulation of the activity of platelet NOS. These include relaxin, a uterine hormone (Bani *et al.*, 1995), and trilinolein, a triacylglycerol obtained from the medicinal herb *Panax pseudoginseng* (Shen and Hong, 1995).

ROLE OF INHIBITORS OF NOS AND NO SCAVENGERS

Inhibitors of NOS (Radomski *et al.*, 1990a) oppose the platelet-inhibitory effects of L-arginine. These compounds shorten bleeding time in humans (Simon *et al.*, 1995) and may precipitate thrombosis under conditions of vascular stress exemplified by septicemia (Schultz and Raij, 1992). Interestingly, long-term smoking impairs the activity of

platelet NOS (Ichiki *et al.*, 1996), although the mechanism responsible for this impairment remains to be elucidated. Purified human hemoglobins, cross-linked to prevent renal damage, are currently undergoing clinical trials as an oxygen-carrying agent. In addition to binding oxygen, hemoglobin has a very high affinity to NO. Olsen and colleagues (1996) showed that cross-linked hemoglobin enhances platelet deposition in a rat carotid endarterectomy model, an effect prevented by administration of L-arginine. Thus, cross-linked hemoglobins may stimulate platelet activation through a mechanism involving NO scavenging.

Interestingly, under some conditions the binding of NO to hemoglobin may be reversible. Stamler and colleagues hypothesized that the binding of NO to the cysteinyl residue of globin in hemoglobin results in the generation of a NO donor agent, which is capable of releasing NO and inhibiting platelet function (Pawloski *et al.*, 1998).

NITRIC OXIDE GAS

Studies using NO gas *in vitro* showed that the molecule was a potent but short-acting (biological half-life < 4 min) inhibitor of platelet adhesion and aggregation and also a stimulator of platelet disaggregation (Radomski *et al.*, 1987a–d). Because of its short-lasting pharmacological effects, inhaled NO is used increasingly as a selective pulmonary vasodilator to treat critically ill adults and infants (for review, see Cheung *et al.*, 1997). Some investigators studied the effects of inhaled NO on platelet function in health and disease. Interestingly, the effects of inhaled NO on platelet function in healthy subjects are not certain (Albert *et al.*, 1996). However, both in adults with adult respiratory distress syndrome (Samama *et al.*, 1995) and in critically ill neonates (Cheung *et al.*, 1998) the NO treatment causes inhibition of platelet function. Under some conditions these effects are unexpectedly long lasting and may enhance the risk of intracranial bleeding. Therefore, caution should be taken during administration of NO gas to critically ill patients.

Interestingly, animal experiments showed that inhaled NO might inhibit the development of coronary thrombosis (Adrie *et al.*, 1996). The pharmacological significance of these findings remains to be investigated.

NITRIC OXIDE DONOR AGENTS

The pharmacological activity of NO donor agents is related to the release of NO (Katsuki *et al.*, 1977; Feelisch and Noack, 1987). The mechanism of NO release from these compounds is spontaneous or is catalyst and enzyme dependent. In contrast to relatively short-lived pharmacological effects of NO gas, those of NO donor agents are longer lasting.

Organic nitrates are poor spontaneous releasers of NO and require the presence of a thiol cofactor for acceleration of this liberation (Feelisch, 1991). However, the *in vivo* release of NO from organic nitrates is greatly enhanced by thiols and enzyme(s) including plasma glutathione-S-transferases (Chen *et al.*, 1996). Whether these or similar enzymes are present in platelets remains controversial (Gerzer *et al.*,

1988; Weber *et al.*, 1996). Nitrate-induced inhibition of platelet aggregation *in vitro* can be greatly potentiated in the presence of thiols or cultured vascular cells (Loscalzo, 1985; Feelisch, 1991; Benjamin *et al.*, 1991). This indicates that the conversion of organic nitrates by the vascular tissue *in vivo* can result in the release of NO in amounts sufficient for inhibition of platelet function. Indeed, in experimental animals, as well as in healthy volunteers, oral and intravenous administration of glyceryl trinitrate and isosorbide mononitrates resulted in inhibition of platelet aggregation *ex vivo* (for review, see Salas *et al.*, 1997a; Plotkine *et al.*, 1991; Werns *et al.*, 1994). The effectiveness of organic nitrates as antithrombotics increases with the extent of vascular injury (Lam *et al.*, 1988). Furthermore, short- and long-lasting administration of nitroglycerin and isosorbide dinitrate to patients suffering from coronary artery disease and acute myocardial infarction resulted in a significant inhibition of platelet adhesion and aggregation (Diodati *et al.*, 1990; Sinzinger *et al.*, 1990).

What is the position of organic nitrates among “classic” inhibitors of platelet function? Aspirin is by far the most widely used antiplatelet drug in clinical practice, and its benefits in terms of decreasing mortality due to repeated infarction have been unequivocally demonstrated (ISIS-2, 1988, ISIS-3, 1992; Patrono, 1989), whereas those of organic nitrates have not yet been established. A meta-analysis found significant reduction in mortality when intravenous glyceryl trinitrate or nitroprusside were used during the acute course of myocardial infarction (Yusuf *et al.*, 1988). Moreover, when combined with *N*-acetylcysteine, glyceryl trinitrate substantially reduced myocardial infarction in unstable angina, an effect compatible with an antiplatelet effect of glyceryl trinitrate (Horowitz *et al.*, 1988). Surprisingly, GISSI III (1994) and ISIS-4 (1993) studies failed to show a clinically beneficial effect of organic nitrates on mortality after myocardial infarction. However, further analysis of GISSI III suggests that the apparent additive effect of glyceryl trinitrate and lisinopril could be attributed to antiplatelet effects of this NO donor agent (R. Andrews *et al.*, 1994). In addition, it is possible that nitrates may act by reducing the infarct size in small rather than large infarcts, so that the neutral results of GISSI-3 and ISIS-4 may be explained by the heterogeneity of effect.

Interestingly aspirin, a cyclooxygenase inhibitor, blocks only thromboxane-mediated platelet aggregation (for references, see Patrono, 1989), leaving the remaining pathways of adhesion and aggregation unopposed. In contrast, NO inhibits the activation cascade of mediators generated by all known pathways of platelet aggregation (Salas *et al.*, 1997a), including matrix metalloproteinase-2-dependent platelet aggregation (Sawicki *et al.*, 1997), and some pathways of platelet adhesion to the subendothelium (Shahbazi *et al.*, 1994).

Whether platelets become tolerant to the platelet-inhibitory effects of organic nitrates is again controversial (Weber *et al.*, 1996; Booth *et al.*, 1996). There have been many attempts to synthesize tolerance-free NO donor agents. One of the

more promising groups of drugs is the cysteine-containing nitrates. Incorporation of a cellular thiol cysteine into the structure of organic nitrate resulted in a high effectiveness of these compounds as inhibitors of platelet and leukocyte functions both *in vitro* and *in vivo* (Lefer *et al.*, 1993).

The phenomenon of tolerance is of lesser pharmacological significance for other NO donor compounds including sodium nitroprusside, molsidomine, and 1,3-morpholino-sydnonimine hydrochloride (SIN-1). Because of its powerful vasodilator action, sodium nitroprusside is often used to treat vascular emergencies associated with hypertensive crisis. Because this compound shows some antiplatelet activity both *in vitro* and *in vivo* (Levin *et al.*, 1982; Hines and Barash, 1989), its acute clinical effects may also be mediated, in part, through inhibition of platelet function. Sodium nitroprusside has been administered intrapericardially to treat experimentally induced coronary thrombosis in dogs (Willerson *et al.*, 1996). The antiplatelet actions of nitroprusside are short lasting, as the release of cyanide from nitroprusside downregulates the pharmacological generation of NO (Brune and Hanstein, 1998). As this route of administration of sodium nitroprusside produced less vasodilation than the systemic route, localized administration of this drug may offer new therapeutic possibilities for the treatment of coronary thrombosis.

Molsidomine and its active metabolite SIN-1 inhibit experimental thrombosis and platelet aggregation in healthy volunteers and in patients suffering from acute myocardial infarction (Wautier *et al.*, 1989). Interestingly, SIN-1 in addition to NO generates superoxide and ONOO⁻ (Hogg *et al.*, 1993). Because ONOO⁻ causes platelet aggregation and counteracts the platelet inhibitory activity of NO (Moro *et al.*, 1994), the formation of this radical may offset the antiplatelet activity of NO released from SIN-1.

NOVEL NO DONORS

The platelet-inhibitory actions of organic nitrates cannot be separated from their effects on the vascular wall. The concept of platelet-selective NO donor agents has arisen from our experiments with *S*-nitrosoglutathione (GSNO) (Radomski *et al.*, 1992). *S*-Nitrosoglutathione is a tripeptide *S*-nitrosothiol that is formed by *S*-nitrosylation of glutathione, the most abundant intracellular thiol. We have found that intravenous administration of GSNO into conscious rats inhibits platelet aggregation at doses that have only a small effect on blood pressure (Radomski *et al.*, 1992). Moreover, similar platelet/vascular differentiation is detected following intraarterial administration of GSNO into the circulation of human forearm (DeBelder *et al.*, 1994). Finally, we have infused GSNO into patients undergoing balloon angioplasty and found that this NO donor agent effectively protected platelets from activation at the site of angioplastic injury without altering blood pressure (Langford *et al.*, 1994). Interestingly, exposure of human neutrophils to NO led to depletion of glutathione stores, activation of the hexose monophosphate shunt, synthesis of endogenous GSNO, and inhibition of superoxide generation by neutrophils. Synthetic

GSNO resulted in similar effects (Clancy *et al.*, 1994). Moreover, the administration of GSNO inhibited leukocyte activation, expression of iNOS, and bypass-induced myocardial lesion in dogs (Mayers *et al.*, 1999).

There is evidence that some of the platelet-regulatory properties of GSNO may also depend on GSNO/glutathione disulfide (GSSG)-stimulated L-arginine transport to platelets (Howard *et al.*, 1998) and may proceed in a cGMP-independent manner (Gordge *et al.*, 1998). These observations show that GSNO is a potent regulator of platelet and neutrophil functions, and it may be a prototype for the development of blood cell-selective NO donor compounds.

Nitro derivatives of aspirin and RGDS peptide have been synthesized in order to capitalize on the synergy of NO with cyclooxygenase inhibitors (aspirin) and the antagonists of the fibrinogen receptor (RGDS) (Wallace *et al.*, 1997; Gurvich *et al.*, 1997). The pharmacological and clinical potential of such hybrid compounds remains to be investigated.

NO-INDEPENDENT ACTIVATORS OF GC-S

Benzylindazole derivatives including 3-(5'-hydroxymethyl-2'-furyl)-1-benzylindazole (YC-1) have been synthesized and shown to be effective inhibitors of platelet adhesion and aggregation (Wu *et al.*, 1995). The pharmacological potential of direct stimulators of GC-S as antithrombotics remains to be studied.

Summary and Conclusions

Research over the past two decades has provided unequivocal evidence for the platelet-regulatory activity of NO generated during physiological and pharmacological reactions. Nitric oxide, thus formed, inhibits platelet adhesion, platelet recruitment, and aggregate formation. Moreover, NO can help in dissipating preformed platelet aggregates and can accelerate the process of repair of the vascular wall. The mechanisms of the remarkable properties of NO are both cGMP dependent and cGMP independent.

Pathological derangement in the generation, action, or metabolism of NO has been shown to contribute to the pathogenesis of occlusive vascular disorders. Exploring potential of NO donor compounds as antithrombotics holds a promise for pharmacological development of potent and platelet-selective therapies of vascular disorders associated with platelet activation and damage.

Pathophysiological Roles of Nitric Oxide in Inflammation

Csaba Szabó

*Inotek Corporation
Beverly, Massachusetts*

LOCAL AND SYSTEMIC INFLAMMATION IS CHARACTERIZED BY THE OVERPRODUCTION OF NITRIC OXIDE (NO). IN MOST INSTANCES, THE SOURCE OF THIS NO IS THE INDUCIBLE ISOFORM OF NO SYNTHASE (iNOS). THE EXPRESSION OF iNOS, WHICH HAS BEEN DEMONSTRATED IN ACTIVATED MACROPHAGES AND IN A VARIETY OF OTHER CELL TYPES IN INFLAMMATION, SERVES TO FIGHT INVADING MICROORGANISMS. HOWEVER, NO PRODUCED BY iNOS ALSO CAN EXERT A VARIETY OF AUTOCRINE CYTOTOXIC EFFECTS. SELECTIVE INHIBITION OF iNOS HAS BEEN SHOWN TO SUPPRESS INFLAMMATION IN A VARIETY OF INFLAMMATORY STATES, INCLUDING ARTHRITIS, COLITIS, ENCEPHALOMYELITIS, AND SYSTEMIC INFLAMMATORY RESPONSE SYNDROME (CIRCULATORY SHOCK). HIGH LOCAL LEVELS OF NO CAN BE TOXIC AND CAN INHIBIT KEY CELLULAR ENZYMES, INCLUDING ENZYMES OF THE MITOCHONDRIAL RESPIRATORY CHAIN. THESE EFFECTS ARE OFTEN DUE TO S-NITROSYLATION REACTIONS.

MANY FORMS OF INFLAMMATION ARE ASSOCIATED WITH THE OVERPRODUCTION OF SUPEROXIDE ANION AS WELL AS NO. THE TOXICITY OF NO INCREASES WHEN IT COMBINES WITH SUPEROXIDE AND FORMS PEROXYNITRITE ANION, A LABILE REACTIVE OXIDANT SPECIES. PEROXYNITRITE CAN REACT VIA A NUMBER OF MECHANISMS WITH PROTEINS, LIPIDS, AND DNA UNDER CONDITIONS OF INFLAMMATION. INITIATION OF LIPID PEROXIDATION AND DIRECT INHIBITION OF VARIOUS KEY ENZYMES IN THE CELL MEMBRANE, MITOCHONDRIA, AND CYTOPLASM CONTRIBUTE TO THE CYTOTOXIC EFFECT OF PEROXYNITRITE. IN ADDITION, PEROXYNITRITE IS A POTENT TRIGGER OF DNA STRAND BREAKAGE, WITH SUBSEQUENT ACTIVATION OF THE NUCLEAR ENZYME POLY(ADP-RIBOSE) SYNTHETASE (PARS), WITH EVENTUAL NECROTIC-TYPE CELL DEATH. NO, OR PEROXYNITRITE, CAN ALSO ENHANCE THE CATALYTIC ACTIVITY OF CYCLOOXYGENASES, WHICH TRIGGERS AND ENHANCES SOME OF THE INFLAMMATORY RESPONSES.

ALTHOUGH NO, DERIVED FROM iNOS, IS GENERALLY VIEWED AS A TERMINAL EFFECTOR OF INFLAMMATION, UNDER CERTAIN CONDITIONS IT CAN ALSO ACT AS AN AMPLIFIER OF PROINFLAMMATORY PATHWAYS. STUDIES UTILIZING iNOS-DEFICIENT MICE CONFIRMED THE CRUCIAL ROLE OF iNOS IN SOME BUT NOT ALL FORMS OF INFLAMMATION. FUTURE WORK, USING SELECTIVE INHIBITORS OF iNOS, IS REQUIRED TO DETERMINE THE EVENTUAL UTILITY OF iNOS INHIBITION FOR THE EXPERIMENTAL THERAPY OF INFLAMMATORY DISEASES IN HUMANS.

Introduction

The production of nitric oxide (NO) in inflammation is generally considered a defense mechanism of the body

against invading microorganisms. Indeed, activated macrophages and neutrophils are able to kill a variety of microorganisms via NO-mediated mechanisms, or via mechanisms that involve a combination of nitrogen- and oxygen-derived

free radicals and oxidants. In this chapter, we do not discuss the roles of NO and related species in host defense, for these topics are subjects of separate chapters in this book. Similarly, we will not discuss, in detail, the defense mechanisms that microorganisms developed against the toxic effects of NO. In this chapter, we will focus on the following issues: (1) the regulation of NO production in inflammation, with special reference to *in vivo* studies, and (2) the mechanisms of the cytotoxic actions of NO, as they relate to injury to the host (i.e., mammalian or human) organism. We will also avoid detailed discussions related to the role of NO in specific inflammatory conditions [such as arthritis, diabetes, encephalomyelitis, and systemic inflammatory response syndrome (circulatory shock)], as these are subjects of separate chapters in this book.

Production of Nitric Oxide in Inflammation

Nitric Oxide Derived from Inducible NO Synthase

INDUCERS OF iNOS EXPRESSION IN INFLAMMATION

In inflammation, proinflammatory cytokines and lipid mediators play a key role in triggering the expression of the inducible isoform of NO synthase (iNOS, or NOS-2) in various cell types. This statement is supported by multiple lines of evidence. (1) A number of proinflammatory cytokines, including tumor necrosis factor α (TNF- α), interleukin 1 β (IL-1 β), γ -interferon (IFN- γ), and interleukin-2 (IL-2), can induce the expression of iNOS *in vitro* or *in vivo*. This usually occurs in an additive or synergistic fashion (for review, see Szabó and Thiernemann, 1995). Although proinflammatory cytokines are generally considered the prime or most important stimuli of iNOS expression, there is also growing evidence that the lipid mediator platelet-activating factor (PAF) can also induce the expression of iNOS in various cell types. For example, PAF and its various analogs have been shown to induce iNOS and enhance lipopolysaccharide (LPS)-induced expression of iNOS in macrophages (Szabó *et al.*, 1993a; Arthur *et al.*, 1995; De Kimpe *et al.*, 1995; Howard and Erickson, 1996). Kupffer cells (Mustafa *et al.*, 1996), rat astrocytes (Cardile *et al.*, 1996), and cultured vascular smooth muscle cells (Arthur *et al.*, 1995). (2) The just mentioned cytokine and lipid mediators are known to be produced in various forms of inflammation. (3) Finally, neutralization of these mediators, by the use of receptor blockers or neutralizing antibodies, suppresses the expression of iNOS in inflammation (Thiernemann *et al.*, 1993a; Szabó *et al.*, 1993a,b; Cunha *et al.*, 1994; Szabó, 1995; De Kimpe *et al.*, 1995; Mustafa *et al.*, 1996; Arthur *et al.*, 1995; Ruetten and Thiernemann, 1997a; Ter Steege *et al.*, 1998; Perkins *et al.*, 1998) (Fig. 1).

The most extensively studied inflammatory condition, with respect to the mechanism of iNOS expression, is systemic inflammation induced by bacterial lipopolysaccharide (i.e., endotoxic shock). The primary initiator of the inflammatory response in gram-negative septic shock is bacterial

LPS (or endotoxin), a component of the bacterial outer membrane. Endotoxins consist of a structurally and antigenically diverse set of series of oligosaccharides that are located in the outermost part of the molecule, including core oligosaccharides, which have a more homogeneous structure, and an innermost lipid part, named lipid A, with a highly conserved structure. According to many reports, lipid A is responsible for most of the immunological and toxic effects of LPS (Freudenberg and Galanos, 1990; Raetz *et al.*, 1991). LPS is a potent stimulator of iNOS expression, which, in many cell types, acts in synergy with IFN- γ (Szabó, 1995; Kilbourn *et al.*, 1997). Lipid A was found to be a weak inducer of iNOS in various cell types (Hattori *et al.*, 1995). However, lipid A was proposed as a good candidate for the elicitation of tolerance against the induction of iNOS by endotoxin (Hattori *et al.*, 1995). Similarly, using a detoxified LPS molecule, one can induce tolerance against the ability of LPS to induce iNOS, without inducing high, potentially toxic levels of iNOS (Gilad *et al.*, 1996).

Although gram-negative bacterial components, chiefly LPS, are the subjects of most investigations focusing on septic shock and systemic inflammation, there is also good evidence that various gram-positive bacterial components can elicit the expression of iNOS *in vitro* and *in vivo* (Freyer *et al.*, 1996; Hirvonen *et al.*, 1997; Orman *et al.*, 1998; Hattori *et al.*, 1997, 1998; Kengatharan *et al.*, 1996, 1998). Importantly, lipoteichoic acid, a component of the membrane of gram-positive bacteria, induces iNOS (Hattori *et al.*, 1997, 1998) in marked synergy with peptidoglycan, another gram-positive membrane component (Kengatharan *et al.*, 1996). Studies have also established that a specific fragment of peptidoglycan, *N*-acetylglucosamine- β (1 \rightarrow 4)-*N*-acetylmuramyl-L-alanine-D-isoglutamine, is the key moiety responsible for the synergism with lipoteichoic acid (or IFN- γ) to induce NO formation in rodent cells (Kengatharan *et al.*, 1998).

Whole gram-positive or gram-negative bacteria have also been shown to elicit the expression of iNOS (Orman *et al.*, 1998; Hirvonen *et al.*, 1998; Witthoft *et al.*, 1998; Salzman *et al.*, 1998; Eaves-Pyles *et al.*, 1999). Bacterial adhesion, rather than invasion appears to be a key factor in the process (Salzman *et al.*, 1998; Eaves-Pyles *et al.*, 1999). The cellular mechanism of iNOS expression involves I κ B degradation and nuclear factor κ B (NF- κ B) activation, as demonstrated in human intestinal epithelial cells (Eaves-Pyles *et al.*, 1999).

CELLULAR MECHANISMS OF iNOS EXPRESSION IN INFLAMMATION

There are relatively few studies on the cellular mechanisms of iNOS expression in inflammation *in vivo*. On the basis of *in vitro* studies (Xie and Nathan, 1994; MacMicking *et al.*, 1997a), it can be assumed that the induction of iNOS *in vivo* is also mediated by tyrosine kinase activation, the activation of NF- κ B, and interferon-regulatory factor-1 (IRF-1), followed by increased expression of iNOS mRNA (Fig. 1). In fact, inhibitors of tyrosine kinases and of NF- κ B activation have been shown to suppress the expression of

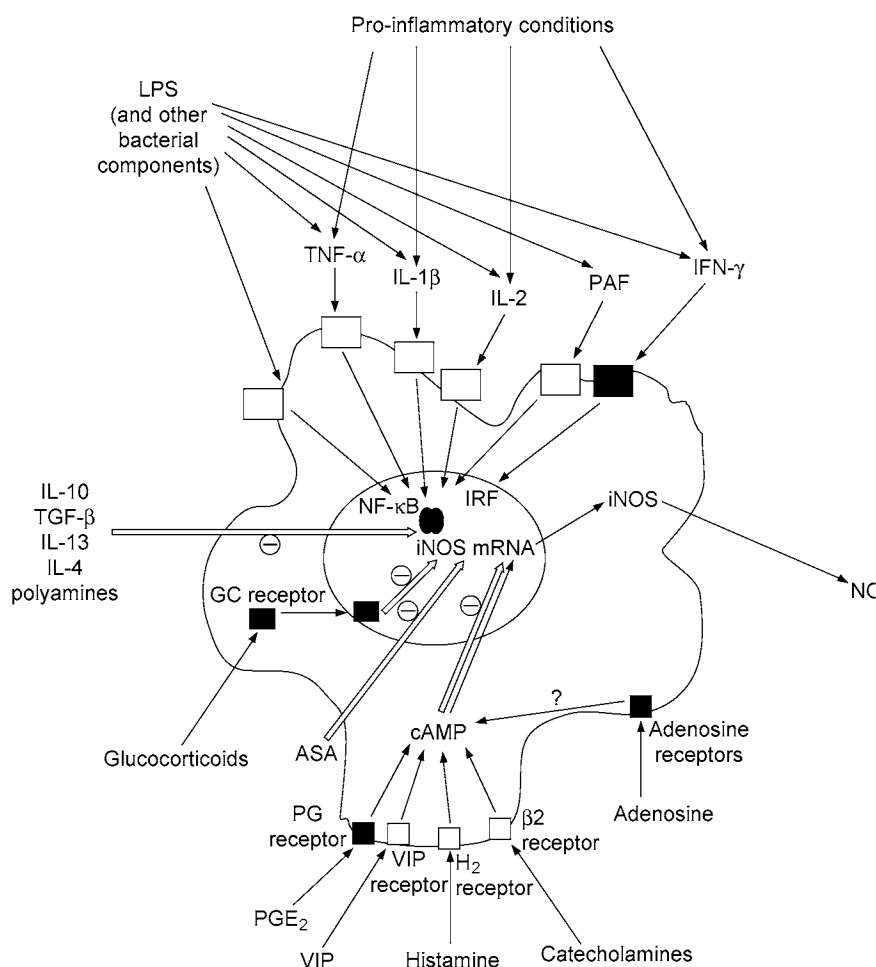

Figure 1 Regulation of iNOS expression in inflammation. Under proinflammatory conditions, proinflammatory cytokines and lipid mediators induce the expression of iNOS in various cell types. Anti-inflammatory mediators can suppress or downregulate the process of iNOS expression. Various mediators that increase intracellular cAMP levels in cells expressing iNOS can increase or decrease iNOS expression, depending on the cell type. The mechanism of iNOS expression, and its regulation, show substantial cell and species differences. Black arrows show activation, open arrows with (–) signs show inhibitory effects. See text for further details.

iNOS in systemic models of inflammation (S. F. Liu *et al.*, 1997; Ruetten and Thiemermann, 1997b,c; Németh *et al.*, 1998; Hong *et al.*, 1998; Kishnani *et al.*, 1999) and also in colitis (Sadowska-Krowicka *et al.*, 1998) and in cardiac allograft rejection (Cooper *et al.*, 1998). Furthermore, studies utilizing IRF-1-deficient mice demonstrated the crucial role of this pathway in the process of iNOS expression in myocarditis (Bachmaier *et al.*, 1997). In accordance with findings derived from *in vitro* studies, iNOS *in vivo* is also regulated at the level of its mRNA stability, which can be exploited to modulate the course of inflammation. For example, treatment of mice with transforming growth factor β (TGF- β) has been used to destabilize iNOS mRNA and suppress the systemic inflammatory response induced by bacterial lipopolysaccharide (Perrella *et al.*, 1996). Mice treated with or overexpressing TGF- β produce less NO in response to a systemic inflammatory stimulus (Pender *et al.*, 1996; Vodovotz *et al.*, 1998), whereas TGF- β -deficient mice have

an abnormally high level of iNOS expression (Vodovotz *et al.*, 1996). There are interactions between TGF- β and α_2 -macroglobulin: α_2 -macroglobulin binds to TGF- β and prevents it from binding to its receptor. Thus, α_2 -macroglobulin can induce iNOS expression, an activity which probably results from the neutralization of autocrine TGF- β activity (Webb *et al.*, 1996). C-reactive protein, which was traditionally considered a marker rather than a mediator of inflammation, has been shown to enhance the expression of iNOS in macrophages (Ratnam and Mookerjee, 1998). On the other hand, the induction of the heat-shock response has been shown to suppress the expression of iNOS (Wong *et al.*, 1995, 1997a,b; Xu *et al.*, 1997; Scarim *et al.*, 1998).

There is some evidence that intracellular cyclic nucleotide levels can also influence the expression of iNOS, although the literature is somewhat conflicting in this respect (Fig. 1). Probably the regulation is dependent on the cell type and possibly the stimulus of iNOS induction. There are a

number of studies, for example, in macrophages, smooth muscle cells, and mesangial cells demonstrating that elevation of intracellular cAMP levels induces iNOS expression or enhances the induction of iNOS (Alonso *et al.*, 1995; Koide *et al.*, 1993; Pang and Hout, 1997; Eberhardt *et al.*, 1998). In contrast, in studies in hepatocytes, Kupffer cells, microglia, and astrocytes, elevation of cAMP levels has been shown to suppress the induction of iNOS (F. S. Smith *et al.*, 1997; Minghetti *et al.*, 1997; Pahan *et al.*, 1997; Mustafa and Olson, 1998; Haskó *et al.*, 1998a,b). On the basis of *in vivo* studies in animals subjected to LPS-induced systemic inflammation, the latter mechanism appears to be more relevant for the pathophysiology of inflammation (i.e., cAMP is an endogenous suppressor of iNOS expression): increases in cAMP levels elicited by adenosine receptor agonists or adrenergic agonists, or by elevation of intracellular cAMP levels by inhibition of cAMP phosphodiesterase inhibitors (e.g., rolipram), suppress the production of NO *in vivo* (Szabó *et al.*, 1997a; Haskó *et al.*, 1998a,b; Haskó and Szabó, 1998).

ENDOGENOUS INHIBITORS OF iNOS EXPRESSION IN INFLAMMATION

Glucocorticoids and IL-10 represent endogenous inhibitors of iNOS expression in inflammation. This conclusion is based on experiments demonstrating the enhanced expression of iNOS in response to LPS in adrenalectomized rats (Szabó *et al.*, 1993c) and in IL-10-deficient mice (Haskó *et al.*, 1998b). Polyamines, melatonin, and a large number of other endogenous molecules have also been shown to inhibit the expression of iNOS *in vitro* (Szabó *et al.*, 1995a; Baydoun and Morgan, 1998; Gilad *et al.*, 1998). *In vitro* studies also demonstrated that a variety of cytokines, such as IL-4 and IL-13, are capable of inhibiting the expression of iNOS (Bogdan *et al.*, 1994; Berkman *et al.*, 1996; Kolios *et al.*, 1998). However, whether the endogenous production of molecules other than cAMP, TGF- β , glucocorticoids, and IL-10 can play a role in regulating the expression or stability of iNOS in inflammation *in vivo* is unclear at the moment (Fig. 1). It needs to be pointed out that there are marked cell and species differences in the regulation of iNOS expression.

TIME COURSE AND SITES OF iNOS EXPRESSION IN INFLAMMATION

The expression of iNOS, in response to a transient stimulus, is transient. For instance, the expression of iNOS in response to systemic administration of bacterial lipopolysaccharide in a rodent peaks at approximately 6 hours and returns to baseline levels by 24 hours (Knowles *et al.*, 1990; Salter *et al.*, 1991; Szabó *et al.*, 1994a). This response is followed by a period of tolerance for the induction of iNOS by subsequent inflammatory stimuli (Szabó *et al.*, 1994a; Chang *et al.*, 1996; Del Castillo *et al.*, 1997), the mechanism of which involves a reduced ability of the cells to express iNOS mRNA (Chang *et al.*, 1996), in part due to upregulation of endogenous glucocorticoids, which suppress the expression of iNOS (Szabó *et al.*, 1994a). Interestingly, the development of tolerance against iNOS induction appears to

be cell type dependent: whereas overall net NO synthesis was found to be downregulated during protracted LPS exposure, aortas and glomeruli maintained most of their ability to express iNOS and produce NO for prolonged periods of time (Del Castillo *et al.*, 1997).

In response to a continuing inflammatory stimulus, there may be a continuing expression of iNOS (albeit probably at lower levels than the initial peak, which develops in response to a sudden single burst of inflammatory mediators). For example, in chronic experimental models of human forms of arthritis or colitis, there is continued increase in the plasma levels of nitrite and nitrate, the breakdown products of NO (Weinberg *et al.*, 1994; Aiko and Grisham, 1995; Stichtenoth *et al.*, 1995; Grabowski *et al.*, 1996; Aiko *et al.*, 1998; Levine *et al.*, 1998; Oudkerk Pool *et al.*, 1995; Pelletier *et al.*, 1998). Similarly, prolonged increases in the levels of nitrite and nitrate can be measured in humans suffering from circulatory shock of various etiologies (Evans *et al.*, 1993; Groeneveld *et al.*, 1996; Krafte-Jacobs *et al.*, 1997).

The induction of iNOS is cell type and organ specific. The most typical cell types that express iNOS in inflammation are macrophages, neutrophils, vascular and nonvascular smooth muscle cells, cardiac myocytes, astrocytes, mesangial cells, epithelial cells, and endothelial cells. These different cell types, depending on the inflammatory condition, can contribute, to a varying extent, to the net NO output of the body (measured as circulating or urinary levels of nitrite/nitrate). For example, in systemic inflammation induced by LPS, the majority of circulating nitrite/nitrate is macrophage derived (Salkowski *et al.*, 1997). This means that measurements of systemic production of NO production do not necessarily reflect the changes in NO production in an individual tissue or organ during inflammation.

Although iNOS is mainly expressed in inflammatory conditions and is not expressed in the absence of inflammatory stimuli in most cell types, there is some evidence for "constitutive iNOS expression" in selected sites of the body. One of these sites is the lung, where epithelial cells of clinically disease-free humans express iNOS (Guo *et al.*, 1995; Guo and Erzurum, 1998). This phenomenon is possibly related to a low-level, physiologically relevant inflammatory activation in this site. Also, iNOS expression has been reported in the thymus of normal animals, and NO or reactive nitrogen species (such as peroxynitrite, see later) formed from NO have been implicated in the process of negative selection in this organ (Virág *et al.*, 1998a; Downing *et al.*, 1998a,b).

PHARMACOLOGICAL OR THERAPEUTIC INHIBITION OF iNOS EXPRESSION IN INFLAMMATION

A number of known anti-inflammatory agents are known to suppress the induction of iNOS. Glucocorticoids are probably the most widely studied from this class of substances. Glucocorticoids are well established as potent inhibitors of the expression of iNOS in rodents *in vitro* and *in vivo* (Radomski *et al.*, 1990; Salter *et al.*, 1991; Szabó *et al.*, 1993d). It is likely that the potent anti-inflammatory action of glucocorticoids in rodents is related to their ability to prevent the

induction of iNOS. However, the human iNOS mRNA expression and proinflammatory cytokine-induced NO production are, according to most studies, largely insensitive to glucocorticoids (Robbins *et al.*, 1994; Salzman *et al.*, 1996; Guthikonda *et al.*, 1998). It is worthwhile to mention that the human chondrocyte may be an exception: at least in some of the *in vitro* studies, iNOS expression in human chondrocytes can be inhibited by steroids (Palmer *et al.*, 1993; Amin *et al.*, 1995a; Cipolletta *et al.*, 1998; de Gendt *et al.*, 1998). This is in agreement with the clinical observations showing that glucocorticoids suppress urinary nitrite/nitrate levels in rheumatic patients (Stichtenoth *et al.*, 1995). With respect to the human iNOS, it is important to point out that its regulation is radically different from the regulation of rodent iNOS. Human iNOS expression (1) is mainly regulated at the level of mRNA stability, rather than at the level of iNOS mRNA expression, and (2) generally requires a costimulation by a mixture of proinflammatory cytokines. Further, the promoter of human iNOS has different regulatory elements, including a distant upstream enhancer element, and also, as mentioned above, iNOS expression is not generally inhibited by glucocorticoids (DeVera *et al.*, 1996; Linn *et al.*, 1997).

Other clinically used well-known anti-inflammatory or immunosuppressive agents that turned out to inhibit the expression of iNOS include cyclosporin A (Shindo *et al.*, 1995; Wu *et al.*, 1998; Trajkovic *et al.*, 1999), methotrexate (Robbins *et al.*, 1998), melatonin (Gilad *et al.*, 1998), tetracyclines (Amin *et al.*, 1996; Trachtman *et al.*, 1996), and the immunosuppressive agent tacrolimus (FK506) (Goto *et al.*, 1997). Nonsteroidal anti-inflammatory agents have also been demonstrated to suppress the expression of iNOS in several cell types. In the first report, it was found that in LPS-stimulated murine macrophages, therapeutic concentrations of aspirin ($IC_{50} = 3 \text{ mM}$) inhibit the expression of iNOS and production of nitrite (Amin *et al.*, 1995b; Amin *et al.*, 1997). In subsequent studies, indomethacin was found to inhibit NO production in immunostimulated macrophages (Pang and Hoult, 1996); aspirin was effective in transformed pancreatic β cells and rat islets (Kwon *et al.*, 1997), aspirin and salicylate in rat fibroblasts (Farivar *et al.*, 1996), and a number of structurally unrelated cyclooxygenase (COX) inhibitors in immunostimulated microglial cells (Minghetti *et al.*, 1997). Furthermore, ibuprofen has been shown to concentration-dependently decrease iNOS mRNA levels and to inhibit the activity of iNOS in glial cells (Minghetti *et al.*, 1997). However, there was no correlation between a decrease in iNOS activity and reduction in iNOS mRNA levels (Stratman *et al.*, 1997). On the basis of earlier work (Grilli *et al.*, 1996; Yin *et al.*, 1998), it is conceivable that the nonsteroidal anti-inflammatory compounds probably exert their effects on iNOS expression, at least in part, by inhibition of the activation of NK- κ B.

EXPRESSION OF iNOS IN HUMAN INFLAMMATORY CONDITIONS

Overall, in humans, the degree of expression of iNOS and the production of NO by iNOS is lower than in many animal

species, especially rodents. This is evidenced by lower levels of plasma nitrite/nitrate in inflammatory conditions and a lower output of NO production in immunostimulated human cells, when compared to immunostimulated rodent cells. Importantly, human monocytes/macrophages, in many early studies, were found not to induce iNOS in response to endotoxin and/or proinflammatory cytokine mixtures, whereas rodent macrophages or macrophage-like cell lines were found to be good expressors of iNOS. Now it is clear that this curious behavior of human monocytes/macrophages is most likely a consequence of inappropriate stimulation conditions in the previously mentioned *in vitro* experiments: cross-linking of CD23 by a monoclonal antibody consistently induces iNOS in human monocytes (Dugas *et al.*, 1998). Similarly, *Mycobacterium tuberculosis* is able to induce iNOS in human monocytes *in vitro* (Jagannath *et al.*, 1998). Furthermore, studies in patients suffering from various forms of inflammation have demonstrated that iNOS is expressed *in situ* in macrophages. A predominant example is a study focusing on the lungs of tuberculous patients, where marked iNOS staining has been demonstrated in resident pulmonary macrophages (MacMicking *et al.*, 1997b; Nicholson *et al.*, 1996). Similarly, enhanced iNOS expression has been demonstrated in neutrophils from patients suffering from urinary tract infection (Wheeler *et al.*, 1997) and septic shock (Tsukahara *et al.*, 1998), in synovial macrophages from arthritic patients (McInnes *et al.*, 1996), in macrophages surrounding aseptic inflammation associated with loosened hip prostheses (Watkins *et al.*, 1997; Hukkanen *et al.*, 1997), and in macrophages infiltrating kidneys of glomerulonephrotic patients (Kashem *et al.*, 1996).

Other human cell types are also known to express iNOS and produce large amounts of NO, including hepatocytes, chondrocytes, and intestinal and pulmonary epithelial cells. Human neutrophils can also be induced *in vitro* to generate significant levels of reactive nitrogen species (Evans *et al.*, 1996; Gagnon *et al.*, 1998). In addition to the previously listed examples, the expression of iNOS (in various cell types) in humans has been demonstrated in a wide variety of conditions including Alzheimer's disease, multiple sclerosis, AIDS-associated dementia, viral uveitis, asthma, lung cancer, pulmonary sarcoidosis, bacterial pneumonia, Crohn's disease, ulcerative colitis, renal allografts, aortic aneurysms, psoriasis, alcoholic hepatitis, and systemic inflammatory response syndrome (circulatory shock) (overviewed in MacMicking *et al.*, 1997a; Kilbourn *et al.*, 1997).

Hepatocytes and intestinal epithelial cells have been the subject of extensive investigations; the promoter of the human iNOS has also been cloned and expressed in these cell types. There is some degree of cell specificity in the regulation, although it is clear that the promoter of the human iNOS gene is radically different from the murine promoter. In the human iNOS promoter, a classic enhancer element is present, which is located between 8.7 and 10.7 kb upstream of the transcription initiation site (Linn *et al.*, 1997). The region between the enhancer element and the transcription initiation site is almost completely silent and uninducible in

human intestinal epithelial cells (Linn *et al.*, 1997), whereas it is somewhat responsive to NF- κ B elements in human liver and lung epithelial cell lines (De Vera *et al.*, 1996; Taylor *et al.*, 1998). As mentioned previously, it is now also evident that the human iNOS is mainly regulated at a posttranscriptional rather than transcriptional level.

Inducible NO Synthase-Independent Sources of NO and Reactive Nitrogen Species in Inflammation

Although it is generally acknowledged that iNOS is the source of most NO produced in various forms of inflammation, it is also clear that sources other than iNOS can also contribute to the production of NO or reactive nitrogen intermediates under certain specialized conditions.

CONSTITUTIVE NOS ISOFORMS

It is now well established, that the “constitutive” NOS isoforms ecNOS (constitutive endothelial NOS) and bNOS (brain NOS) can also undergo transcriptional regulation (Förstermann *et al.*, 1995). Examples of upregulation of ecNOS-like proteins in inflammation-related conditions include cyclosporin-treated renal transplant patients (Calo *et al.*, 1998), chronic heart failure (Khadour *et al.*, 1998), hepatic cirrhosis (Martin *et al.*, 1996), iron-deficiency anemia (Ni *et al.*, 1997), and hemorrhagic shock (Zingarelli *et al.*, 1998a). In the latter two conditions, increased levels of both ecNOS as well as iNOS (see below) were found (Ni *et al.*, 1997; Zingarelli *et al.*, 1998a). Estrogen and vascular endothelial growth factor (VEGF) may serve as physiologically or pathophysiologically relevant upregulators of ecNOS (MacRitchie *et al.*, 1997; Hood *et al.*, 1998).

Even in the absence of transcriptional or posttranscriptional regulation of the constitutive isoforms of NOS, physiological levels of NO can be converted to potentially cytotoxic species. All three isoforms of NO synthase, namely, ecNOS, bNOS, and iNOS, can contribute to the production of NO with subsequent formation of reactive nitrogen species, such as peroxynitrite (a labile potent oxidant, produced by the reaction of NO and superoxide; see also later). For instance, superoxide, produced during the reperfusion phase of ischemia–reperfusion injury or in the acute phase of shock, reacts with NO produced from constitutive, presumably endothelial NOS, thereby forming peroxynitrite (Szabó *et al.*, 1995a,b; Wang and Zweier, 1996; Zingarelli *et al.*, 1997a). Under these conditions, formation of superoxide, and not that of NO, is the rate-limiting step in the formation of peroxynitrite. In various forms of neuroinjury, bNOS activation precedes the formation of peroxynitrite (Dawson, 1995; Szabó, 1996; Dawson and Dawson, 1996; Bolanos *et al.*, 1997).

It is important to point out that under certain conditions, all isoforms of NOS are capable of producing both precursors of peroxynitrite (in the form of simultaneous generation of NO and superoxide). Such conditions cannot be found under normal circumstances, but they can occur during cellular L-arginine depletion. Massive activation of NOS can

deplete the cellular levels of its precursor L-arginine (despite an activation of an enzyme system, which recycles the end product L-citrulline back to arginine, and upregulation of membrane L-arginine transport mechanisms). Under low cellular arginine concentrations, NOS produces both NO and superoxide, and the resulting generation of peroxynitrite can contribute to cytotoxicity. This mechanism has been confirmed in neuronal cultures, and in macrophages expressing iNOS (Xia *et al.*, 1996; Xia and Zweier, 1997).

NONENZYMATIC PATHWAYS

In addition to enzymatic sources, it is possible that the reduction of nitrite to NO under acidic conditions (Zweier *et al.*, 1995) can eventually lead to generation of peroxynitrite in certain forms of inflammation. Moreover, a recently described, nonenzymatic pathway generating NO from L-arginine and hydrogen peroxide may also be considered (Nagase *et al.*, 1997). We include these two nonenzymatic processes of NO generation for the purpose of completeness. Further investigations are required to elucidate whether these latter processes can significantly contribute to NO or peroxynitrite generation in physiology or pathophysiology.

MYELOPEROXIDASE-CATALYZED TOXIC PROCESSES INVOLVING NITRITE

Tyrosine nitration is considered one of the key mechanisms through which peroxynitrite can induce inflammatory posttranscriptional modification of proteins (see later). Van Der Vliet *et al.* (1997) have established that nitrite, a major end product of NO metabolism, can also promote tyrosine nitration through formation of nitryl chloride (NO₂Cl) and nitrogen dioxide by reaction with the inflammatory mediators hypochlorous acid (HOCl) or myeloperoxidase. Activated human polymorphonuclear neutrophils convert nitrite NO₂Cl and nitrogen dioxide through myeloperoxidase-dependent pathways. Polymorphonuclear neutrophil-mediated nitration and chlorination of tyrosine residues or 4-hydroxyphenylacetic acid is enhanced by addition of nitrite. The physiological significance of these reaction pathways to cellular dysfunction has been established by studies demonstrating that polymorphonuclear neutrophil-mediated inactivation of endothelial cell angiotensin-converting enzyme is exacerbated by nitrite (Eiserich *et al.*, 1996, 1998).

Another myeloperoxidase-mediated process involving nitrite and hydrogen peroxide is related to the covalent cross-linking of immune complexes. This process is known to be catalyzed by activated neutrophils, and it exclusively requires nitrite (and not NO) (Uesugi *et al.*, 1998). As oxygen radicals and NO are likely to interact at the cartilage surface during inflammatory arthritis, the resulting immune complex cross-linking may have important pathophysiological consequences. It is important to note that nitrite, which previously was considered an innocuous degradation product of NO, is now also recognized as a species capable of regulating inflammatory processes through various myeloperoxidase-mediated oxidative mechanisms. From the standpoint of therapeutic intervention, the presence of nitrite-dependent

cytotoxic pathways may indicate that appropriate strategies which prevent the overproduction of NO in inflammation may be more desirable than the use of agents which react with NO or peroxynitrite and catalyze their decomposition to nitrite and nitrate.

Mechanisms of the Detrimental Actions of Nitric Oxide in Inflammation

Nitric Oxide-Mediated Effects

Large concentrations of locally produced NO are historically considered to have large cytotoxic potential. It is becoming increasingly clear, however, that the intrinsic oxidant capacity of “pure” NO is low. In other words, although many studies concluded that NO itself is able to induce cytotoxic or cytostatic effects (such as the suppression of the mitochondrial respiratory chain, or induction of cell necrosis and apoptosis), these studies should be viewed with some caution: the formation of superoxide is present in many experimental systems, and the production of peroxynitrite (from the extremely rapid reaction of NO and superoxide) may ultimately mediate many of the toxic or pro-oxidant actions of NO.

CYCLIC GMP-RELATED EFFECTS OF NO IN INFLAMMATION

Pure NO or nitrosothiols are generally responsible for physiological processes, such as vasodilation, via a mechanism that involves activation of guanylyl cyclase in the vascular smooth muscle cells (Ignarro, 1991). Large concentrations of NO, produced by iNOS, can cause autocrine or paracrine actions that can be considered as an “overactivation” of the same physiological process that is normally regulated by NO produced from eNOS. A classic example of this process is the toxic, therapy-resistant, systemic vasodilation associated with systemic inflammatory response syndrome (circulatory shock). In this case, a normal, physiological cGMP-dependent vasodilatory effect is pathophysiologically enhanced by the higher local levels of iNOS-derived NO (Szabó, 1995; Kilbourn *et al.*, 1997). Another example of a cGMP-mediated process is the inhibition of neutrophil or platelet adhesion to the endothelial surface, which is a process normally related to NO production from endothelial NOS (Radomski *et al.*, 1987; Kubes *et al.*, 1991). However, during inflammation, iNOS-derived NO can exert similar effects, which, in this case, can be considered beneficial (Shultz and Raji, 1992; Yan *et al.*, 1996; Hickey *et al.*, 1997; Binion *et al.*, 1998).

S-NITROSYLATION-RELATED EFFECTS OF NO IN INFLAMMATION

The chemical reactions of NO are largely dictated by its redox state. Increasing evidence suggests that the various redox states of the NO group exist endogenously in biological tissues. In the case of nitrosonium cation (NO⁺) equivalents, the mechanism of reaction often involves S-nitrosylation (transfer of the NO group to a cysteine sulfhydryl to form an

RS-NO), and further oxidation of critical thiols can possibly form disulfide bonds. Some of the first physiological and chemical evidence for the potential regulation of pathophysiological processes by NO-mediated S-nitrosylation was related to the regulation of the activity of the *N*-methyl-D-aspartate (NMDA) receptor, a key receptor in various forms of neuroinflammatory conditions. Now it is clear that NMDA receptor activity can be modulated by S-nitrosylation, resulting in a decrease in channel opening (Lipton *et al.*, 1993, 1998). However, other data also suggest that NO, probably in the singlet (or high-energy) state, can also react with critical sulfhydryl group(s) of the NMDA receptor to downregulate its activity, whereas in the triplet (lower-energy) state nitroxyl anion (NO⁻) may oxidize these NMDA receptor sulfhydryl groups by the formation of an intermediate such as peroxynitrite (Lipton *et al.*, 1993, 1998). Inhibition of NMDA receptor activation can be considered as a beneficial (anti-inflammatory) function of NO in neuroinflammatory conditions, whereas activation of this receptor is detrimental, because it enhances neuronal calcium overload and NO and oxyradical production.

S-Nitrosylation by NO of key proteins of various signal transduction pathways has been reported in a number of experimental systems; the enzymes affected include protein kinase C (Gopalakrishna *et al.*, 1993; Akesson and Lundquist, 1998), c-Jun N-terminal kinase 2 (So *et al.*, 1998), tyrosine kinase (Estrada *et al.*, 1997), and various intracellular calcium release channels (Campbell *et al.*, 1996; Favre *et al.*, 1998; Xu *et al.*, 1998). The S-nitrosylation of the transcription factor NF- κ B p50 has been shown to lead to a significant decrease in DNA binding (DeLaTorre *et al.*, 1998). NO, probably via S-nitrosylation, has also been shown to reduce the DNA binding of the transcription factor c-Myb (Brendeford *et al.*, 1998). Similarly p21(ras) and activator protein 1 (AP-1) have been shown to be regulated by S-nitrosylation (Lander *et al.*, 1997; Tabuchi *et al.*, 1994). These S-nitrosative processes, if they also occur *in vivo*, may result in an enhancement of the dysregulation of cellular signal transduction processes, which may exacerbate the course of inflammation.

S-Nitrosylation and subsequent inactivation of enzymes involved in biosynthetic processes, for example, methionine adenosyltransferase (Ruiz *et al.*, 1998) and glyceraldehyde-3-phosphate dehydrogenase (Padgett and Whorton, 1997), have also been reported. These effects are most likely detrimental in inflammation.

S-Nitrosylation of mitochondrial complex I (Clementi *et al.*, 1998) would also be expected to have deleterious effects on cellular energetics. Low (nanomolar) levels of NO reversibly inhibit mitochondrial respiration by binding to the oxygen binding site of cytochrome oxidase in competition with oxygen. This raises the apparent K_m for oxygen of mitochondrial respiration into the physiological range, potentially making respiration sensitive to the oxygen level. The NO inhibition of oxygen consumption was seen in isolated cytochrome oxidase, mitochondria, brain nerve terminals, and cultured cells. These observations suggest that any cell

producing high levels of NO will inhibit its own respiration and that of surrounding cells, which makes the respiration rate sensitive to the oxygen level. This NO-related inhibition of energy metabolism may contribute to cytotoxicity or cyto-

stasis in some pathophysiological conditions (Brown, 1997) (Fig. 2). Endogenously produced, low levels of NO regulate tissue oxygen extraction under resting conditions (Wolin *et al.*, 1999). NO and peroxynitrite also inhibit the activity of

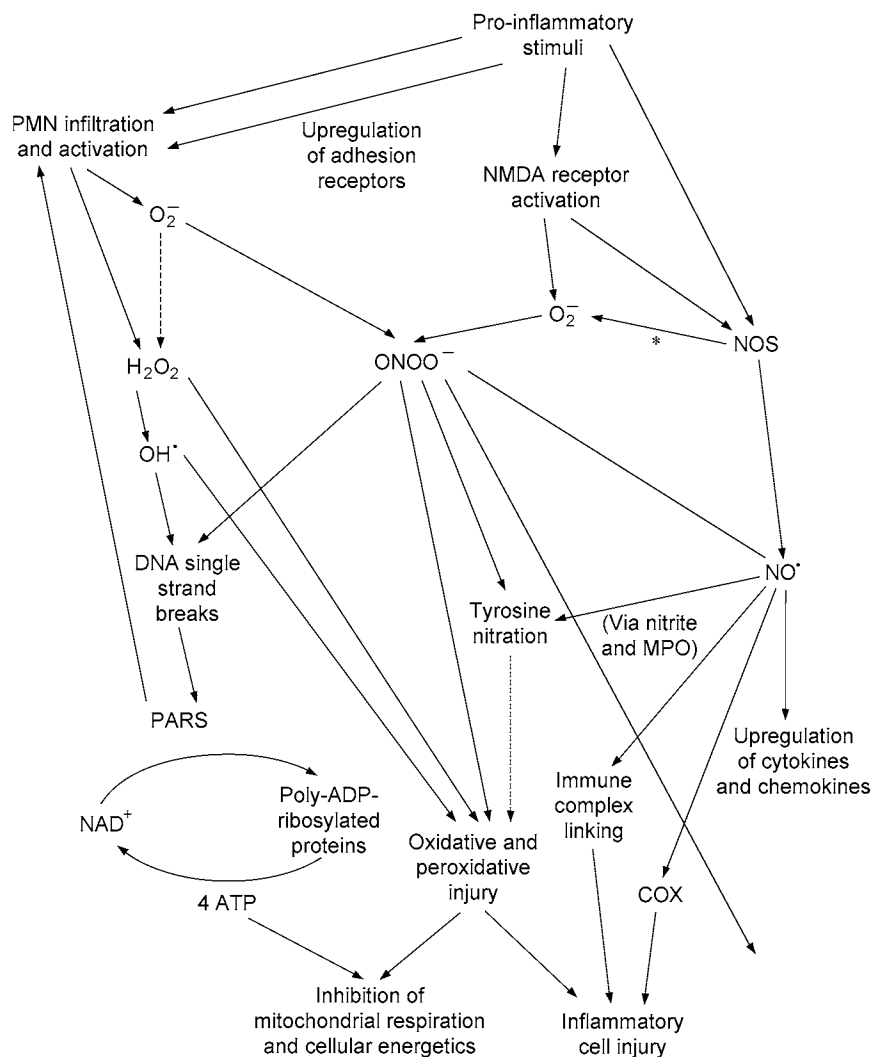

Figure 2 Proposed scheme of PARS-dependent and PARS-independent cytotoxic pathways involving nitric oxide (NO^\cdot), hydroxyl radical (OH^\cdot), and peroxynitrite ($ONOO^-$) in inflammation. Proinflammatory mediators induce the expression of the inducible NO synthase (iNOS), whereas NMDA receptor ligands activate the constitutive neuronal NOS (bNOS). NO, in turn, combines with superoxide to yield peroxynitrite. Hydroxyl radical (produced from superoxide via the iron-catalyzed Haber-Weiss reaction) and peroxynitrite or peroxynitrous acid induce the development of DNA single-strand breakage, with consequent activation of PARS. Depletion of the cellular NAD^+ leads to inhibition of cellular ATP-generating pathways, leading to cellular dysfunction. NO alone does not induce DNA single-strand breakage, but it may combine with superoxide (produced from the mitochondrial chain or from other cellular sources) to yield peroxynitrite. Under conditions of low cellular L-arginine, NOS may produce both superoxide (*) and NO, which then can combine to form peroxynitrite. There are PARS-independent, parallel pathways of cellular metabolic inhibition, and these pathways can be activated by NO, hydroxyl radical, superoxide, and peroxynitrite (alone or in combination or synergy). For instance, peroxynitrite can induce cell injury via protein tyrosine nitration. Tyrosine nitration can also be induced by an alternative pathway utilizing myeloperoxidase (MPO) and nitrite. A similar pathway can also result in immune complex cross-linking. In inflammation, activation of cyclooxygenase (COX) by NO or peroxynitrite may also amplify the inflammatory response. PARS activation promotes neutrophil (PMN) recruitment, thereby triggering a positive feedback cycle. NO, in addition to being a terminal effector of inflammation, also acts as an amplifier of the inflammatory response. See text for further details.

aconitase in various cell types (Castro *et al.*, 1998; Gardner *et al.*, 1997, 1998a; Hausladen and Fridovich, 1994; Castro *et al.*, 1994). It appears that most of the detrimental effects of NO on mitochondrial respiration and cellular energetics occur via peroxynitrite-mediated processes (see later).

Several independent groups of investigators have reported that caspases (key proapoptotic effector enzymes) become S-nitrosylated and inactivated by NO. This reaction leads to a subsequent suppression of apoptotic DNA fragmentation (Melino *et al.*, 1997; Li *et al.*, 1997; Kim *et al.*, 1997, 1998a; Ceneviva *et al.*, 1998). The suppression of apoptosis by NO may be beneficial or detrimental, depending on the particular cell type involved in apoptosis and the specific form of inflammatory condition. Another protein that may be important in the process of apoptosis and that has been shown to be regulated by NO and S-nitrosylation is transglutaminase (Melino and Piacentini, 1998).

Another example of S-nitrosylation with potential implications for inflammation is related to the affinity of the glucocorticoid receptor. This receptor is known to have critical cysteine residues for steroid binding in its hormone-binding and DNA-binding domains. It has been demonstrated that NO, most likely by S-nitrosylation, reduces the ability of ligands to bind to the glucocorticoid receptor (Galigniana *et al.*, 1999). This mechanism, if also operative *in vivo*, may have implications for the regulation by glucocorticoids of iNOS expression and for the steroid regulation of many other pathways of inflammation.

NO can also polynitrosylate proteins, such as albumin (Stamler *et al.*, 1992; Simon *et al.*, 1996), and can react with hemoglobin to form nitrosohemoglobin (Stamler *et al.*, 1997). These reactions in inflammation may be beneficial, because the proteins may act as “sponges” to remove NO from sites where it is produced in high local levels. These proteins may also transport the NO to other parts of the body, where it may be released without significant cytotoxic effects.

Peroxynitrite-Mediated Effects

EVIDENCE FOR THE PRODUCTION OF PEROXYNITRITE IN INFLAMMATION

Although the investigations into the effects of exogenously administered peroxynitrite in cells and tissues are relatively straightforward from a technical point of view, there are a number of problems related to the detection of endogenously produced peroxynitrite. Similarly, there are theoretical and experimental difficulties related to the delineation of the actual role of peroxynitrite in pathophysiological conditions. Some of these limitations are discussed in this section.

Theoretical considerations strongly favor the production of peroxynitrite when NO and superoxide are produced simultaneously. The reaction of these two species is nearly diffusion controlled. Furthermore, the reaction of superoxide with NO is the only reaction that outcompetes the reaction of superoxide with superoxide dismutase (Beckman *et al.*, 1990; Pryor and Squadrito, 1995; Beckman and Koppenol, 1996). Although chemical considerations favor the produc-

tion of peroxynitrite, the actual demonstration of the presence or production of peroxynitrite in pathophysiological conditions is far from straightforward. Peroxynitrite rapidly oxidizes the fluorescent probe dihydrorhodamine 123 to rhodamine 123 *in vitro* (Kooy *et al.*, 1995a). The production of peroxynitrite can be evidenced as increased oxidation of dihydrorhodamine 123 to rhodamine 123 in the plasma (Szabó *et al.*, 1995b). Caution should be exercised with this method, however: oxidation of dihydrorhodamine can be triggered by oxidants other than peroxynitrite (e.g., hydroxyl radical). A NOS inhibitor-inhibitable component of an increased oxidation of dihydrorhodamine can be taken as a relatively specific evidence of an effect of peroxynitrite (Szabó *et al.*, 1995b; Cuzzocrea *et al.*, 1997).

Nitrotyrosine formation, and its detection by immunostaining, was initially proposed as a relatively specific means for detection of the “footprint” of peroxynitrite (Ischiropoulos *et al.*, 1992a). On the other hand, as discussed earlier, more recent evidence indicates that certain other reactions can also induce tyrosine nitration; for example, the reaction of nitrite with hypochlorous acid and the reaction of myeloperoxidase (and certain other peroxidases) with hydrogen peroxide can lead to the formation of nitrotyrosine (Eiserich *et al.*, 1996, 1998; Van Der Vliet *et al.*, 1997). The physiological or pathophysiological relevance of this reaction remains to be further clarified. Increased nitrotyrosine staining was considered an indication of “increased nitrosative stress,” rather than a specific marker of peroxynitrite (Halliwell, 1997). Nitrated tyrosine residues have been demonstrated in a wide variety of inflammatory and shock conditions, including arthritis, colitis, uveitis, allergic encephalomyelitis, and systemic inflammation or circulatory shock (e.g., Kaur and Halliwell, 1994; Wizemann *et al.*, 1994; Szabó *et al.*, 1995a,b; Abe *et al.*, 1995, 1997; Miller *et al.*, 1995; Akaike *et al.*, 1996; Singer *et al.*, 1996; Kooy *et al.*, 1995b, 1997; Brujin *et al.*, 1997; Van Der Veen *et al.*, 1997; Saleh *et al.*, 1997; Zingarelli *et al.*, 1997a, 1998a; overviewed in Szabó, 1996).

Specific peroxynitrite scavengers, which could help in delineating the specific role of peroxynitrite in inflammation or shock or in any other pathophysiological condition, are not generally available. Agents that scavenge peroxynitrite often neutralize other oxidants as well (e.g., glutathione, melatonin; see earlier). Uric acid, a putative scavenger of peroxynitrite, is sometimes used as a probe for peroxynitrite (Kooy *et al.*, 1995a; Szabó and Salzman, 1995; Szabó *et al.*, 1996a; Xie and Wolin, 1996; Johnson and Ferro, 1996; Hooper *et al.*, 1997; Xia and Zweier, 1997). However, uric acid can interfere with a number of other oxidants (Ames *et al.*, 1981; Frei *et al.*, 1989), and therefore caution should be applied when interpreting the results obtained with uric acid. A novel class of peroxynitrite decomposition catalysts has been identified; these compounds, indeed, exert potent anti-inflammatory actions (Salvemini *et al.*, 1998).

Taken together, the evidence implicating the role of peroxynitrite in a given inflammatory condition can only be indirect. A simultaneous protective effect of superoxide

neutralizing strategies and NO synthesis inhibition, coupled with the demonstration of the production of peroxynitrite (via one or more of the previously listed indirect methods) in the particular inflammatory condition, can be taken as strong indication for the role of peroxynitrite. However, it is likely that additional interactions of oxygen- and nitrogen-derived free radicals also contribute to the inflammatory cell injury, possibly in concert or in synergy.

OXIDATION, NITRATION, AND NITROSATION INDUCED BY PEROXYNITRITE

In vitro experiments have demonstrated that peroxynitrite is highly reactive (Fig. 2). The oxidant reactivity of peroxynitrite is mediated by an intermediate with the biological activity of hydroxyl radical, which is not hydroxyl radical per se, but rather peroxynitrous acid or its activated isomer (Pryor and Squadrito, 1995; Pou *et al.*, 1995; Beckman and Koppenol, 1996; Goldstein *et al.*, 1996). Peroxynitrite induces the oxidation of sulfhydryl groups and thioethers, and it induces nitration and hydroxylation of aromatic compounds, such as tyrosine, tryptophan, and guanine (Ischiropoulos *et al.*, 1992a; Salman-Tabcheh *et al.*, 1995; Alvarez *et al.*, 1996; Beckman, 1996; Radi, 1996; Kato *et al.*, 1997). These reactions, when occurring during the reaction of peroxynitrite with various enzymes of the cell, can markedly suppress the catalytic activity of the affected enzymes. For instance, peroxynitrite has been shown to inhibit manganese superoxide dismutase, tyrosine hydroxylase, membrane Na^+, K^+ -ATPase, membrane sodium channels, glyceraldehyde-3-phosphate dehydrogenase, mitochondrial and cytosolic aconitase, and a number of critical enzymes in the mitochondrial respiratory chain (Bauer *et al.*, 1992; Ischiropoulos *et al.*, 1995a; Hausladen and Fridovich, 1994; Castro *et al.*, 1994; Mohr *et al.*, 1994; Hu *et al.*, 1994; Radi *et al.*, 1994; Rubbo *et al.*, 1994; Crow and Beckman, 1995; Guzman *et al.*, 1995; Bolanos *et al.*, 1995; Selden *et al.*, 1995; MacMillan-Crow *et al.*, 1996; Cassina and Radi, 1996; Lizasoain *et al.*, 1996; Sato *et al.*, 1997). Tyrosine nitration in neutrophils has been shown to enhance the responsiveness of the cells to express and produce inflammatory mediators in response to subsequent proinflammatory stimuli (Rohn *et al.*, 1999). Peroxynitrite also exerts a feedback inhibitory effect on NO synthase (Pasquet *et al.*, 1996; Huhmer *et al.*, 1997).

Nitrotyrosine serves as a relatively specific marker of peroxynitrite production *in vivo*, although, as mentioned earlier, other pathways such as the reaction of nitrite and myeloperoxidase can also result in tyrosine nitration (Van Der Vliet *et al.*, 1997; Eiserich *et al.*, 1998). Until very recently, it was presumed that the nitration of tyrosine, and thus the nature of the inhibition of the affected enzymes by peroxynitrite, was irreversible. However, in a pioneering line of work, Murad and colleagues identified an LPS-inducible putative enzyme from the supernatant of spleen homogenates. This enzymatic activity catalyzes the loss of the nitrotyrosine epitope without protein degradation. Although the product and possible cofactors for this reaction have not yet been identified, this activity, which may be a "nitrotyrosine denitrase"

that reverses protein nitration, would be expected to act as an anti-inflammatory enzyme that serves to decrease or reverse peroxynitrite toxicity (Kamisaki *et al.*, 1998).

In addition to the interactions of peroxynitrite with proteins, an important interaction of peroxynitrite occurs with nucleic acids (for review, see Szabó and Ohshima, 1997). Two main types of reactions have been described: DNA base modifications and DNA single-strand breakage. The reported base modifications include the formation of 8-nitroguanine, 8-oxoguanine, and 4,5-dihydro-5-hydroxy-4-(nitrosooxy)-2'-deoxyguanosine (nox-dG), and the formation of oxidized and deaminated base products, such as 5-hydroxyhydantoin, 5-(hydroxymethyl)uracil, thymine glycol, 4,6-diamino-5-formamidepyrimidine (FAPy-adenine), 2,6-diamino-5-formamidepyrimidine (FAPy-guanine), 8-oxo-adenine, 8-oxoguanine, hypoxanthine, and xanthine (Inoue and Kawanishi, 1995; Yermilov *et al.*, 1995, 1996; Spencer *et al.*, 1996; Uppu *et al.*, 1996; Kennedy *et al.*, 1997). The peroxynitrite-induced DNA single-strand breakage (King *et al.*, 1992; Salgo *et al.*, 1995a; Szabó *et al.*, 1996a,b) is probably related to abstraction of hydrogen atoms from the ribose of the DNA moiety, thereby opening the sugar ring. Single-strand breaks of the DNA induce the activation of the nuclear enzyme poly(ADP-ribose) synthetase, with concomitant cellular energy depletion and cell necrosis (see later).

Some of the biological actions of peroxynitrite are summarized in Table I. These effects can manifest in many ways in intact cells. For instance, in pulmonary type II cells, inhibition by peroxynitrite of membrane Na^+, K^+ -ATPase activity and sodium uptake has been reported (Hu *et al.*, 1994). In neurons, glial cells (Bolanos *et al.*, 1995), cultured macrophages (Zingarelli *et al.*, 1996; Szabó *et al.*, 1996b), cultured rat aortic smooth muscle cells (Szabó *et al.*, 1996a), endothelial cells (Szabó *et al.*, 1997b), epithelial cells (Szabó *et al.*, 1997c; Kennedy *et al.*, 1998), as well as a number of other cell types, profound inhibition by peroxynitrite of mitochondrial respiration has been observed, with inhibition of NADH-coenzyme Q1 reductase, succinate-cytochrome *c* reductase, and cytochrome *c* oxidase activities. In macrophages, smooth muscle cells, epithelial cells, and endothelial cells, peroxynitrite induces a marked reduction of intracellular NAD^+ and ATP levels (Szabó *et al.*, 1996a,b, 1997c; Kennedy *et al.*, 1998).

Mechanistically, peroxynitrite or NO generation from exogenous or endogenous sources can ultimately lead to necrotic or apoptotic cell death. Whereas higher levels of sudden oxidant bursts tend to induce necrosis, lower levels with longer times of exposure tend to lead to cell death via the apoptotic pathway (Bonfoco *et al.*, 1995; Lin *et al.*, 1995; Estevez *et al.*, 1995; Salgo *et al.*, 1995a,b; Sandoval *et al.*, 1996). Several independent groups have reported that caspase-3, a mediator of apoptosis, but not caspase-1, becomes activated in cells exposed to peroxynitrite: its pharmacological inhibition suppresses peroxynitrite-induced apoptotic DNA fragmentation (Virág *et al.*, 1998a,b; Lin *et al.*, 1998). The activation of caspases may be related to the release of cytochrome *c* from the mitochondria induced by peroxynitrite.

Table I Selected Detrimental Actions of NO or Peroxynitrite in Inflammation

Effect	Mechanism of action
Toxic vasodilation	cGMP, energetic failure
Toxic myocardial effects	cGMP, energetic failure
Inhibition of cellular respiration	Multiple (S-nitrosylation, peroxynitrite)
Cell necrosis	Peroxynitrite, PARS
Apoptosis	Multiple: peroxynitrite, NO, caspase activation, transglutaminase
Inhibition of biosynthetic pathways	Multiple
Signal transduction disturbances	Multiple (S-nitrosylation, peroxynitrite, interaction with sulfhydryl groups, tyrosine nitration)
Endothelial dysfunction	Multiple (peroxynitrite, PARS)
NMDA receptor activation	Peroxynitrite
Inhibition of glucocorticoid receptor affinity	S-Nitrosylation
Activation of cyclooxygenases	Peroxynitrite
Inflammatory pain development	Multiple, in part cGMP-dependent
Inflammatory plasma extravasation	Multiple, in part cGMP-dependent
Priming of neutrophil activation	Peroxynitrite, tyrosine nitration
Amplification of signal transduction pathways	Multiple, peroxynitrite dependent
Inhibition and inactivation of antioxidant systems	Multiple, peroxynitrite (in part)
Damage to lipids	Peroxynitrite-mediated peroxidation
DNA nicking, DNA strand breakage	Peroxynitrite-mediated oxidation
Inhibition of DOPA biosynthesis	Tyrosine nitration of tyrosine hydroxylase
Activation of PARS	DNA single-strand breakage.

It is noteworthy that, although the predominant actions of peroxynitrite are cytotoxic, small amounts of peroxynitrite are produced under basal, physiological conditions (since, in many cell types, NO from the constitutive NOS isoforms and superoxide from mitochondria and other cellular sources are always produced) (Kelm *et al.*, 1997). It is probable that the endogenous antioxidant systems are sufficient to neutralize such low-level peroxynitrite production (and, possibly, convert it to NO donor agents; see later). Therefore, low levels of peroxynitrite are not cytotoxic, or they even may be cytoprotective. For example, low levels of peroxynitrite have been shown to inhibit neutrophil adhesion (Lefer *et al.*, 1997). Under these conditions, peroxynitrite is likely to form NO adducts with glucose, thiols, and other species (Moro *et al.*, 1994, 1995), which, in turn, can act as NO donor compounds, which can exert cytoprotective effects by activating guanylyl cyclase (Tarpey *et al.*, 1995; Mayer *et al.*, 1995; Davidson *et al.*, 1997) or by other mechanisms.

THE PEROXYNITRITE-POLY(ADP-RIBOSE) SYNTHETASE PATHWAY

In addition to direct cytotoxic effects, an indirect pathway of peroxynitrite-induced cellular injury has been proposed. The generation of peroxynitrite, either intracellularly or extracellularly, has been shown to trigger DNA single-strand breakage and the activation of the nuclear enzyme poly(ADP-ribose) synthetase [PARS, also termed poly(ADP-ribose) polymerase or PARP]. The importance of this pathway is reviewed in detail elsewhere (Cochrane, 1991; Szabó and Dawson, 1998; Szabó *et al.*, 1998). Briefly, DNA single-strand breakage is the obligatory trigger of activation of PARS. When activated, PARS catalyzes the cleavage of NAD⁺ to ADP-ribose and nicotinamide. PARS covalently attaches ADP-ribose to various nuclear proteins, such as histones and PARS itself. Activation of PARS can rapidly deplete NAD⁺, slowing the rate of glycolysis, electron transport, and ATP formation, resulting in cell dysfunction. These processes can lead to necrotic cell death (Heller *et al.*, 1995; Eliasson *et al.*, 1997; Virág *et al.*, 1998a–c).

Pharmacological inhibition of PARS activity protects against cell damage in response to exogenously or endogenously produced peroxynitrite (Szabó *et al.*, 1996b, 1997b–d; Kennedy *et al.*, 1998; Virág *et al.*, 1998a–c). *In vivo*, inhibition or genetic inactivation of PARS has been shown to protect against inflammatory cell injury and disease development in arthritis (Miesel *et al.*, 1994, 1996; Kroger *et al.*, 1996; Szabó *et al.*, 1998), colitis (Kennedy *et al.*, 1998; Zingarelli *et al.*, 1999), allergic encephalomyelitis (Scott *et al.*, 1998), endotoxic and hemorrhagic shock (Szabó *et al.*, 1996a; 1997d–f), and diabetes (Heller *et al.*, 1995; Burkart *et al.*, 1999; Masutani *et al.*, 1999). PARS^{-/-} animals were also found resistant against zymosan-induced inflammation and multiple organ failure when compared to the response of wild-type mice (Szabó *et al.*, 1997d), and they were also resistant against colitis (Zingarelli *et al.*, 1999) and reperfusion injury of the brain and heart (Endres *et al.*, 1997; Eliasson *et al.*, 1997; Zingarelli *et al.*, 1998b). The role of PARS in various inflammatory conditions is overviewed elsewhere (Szabó, 1998).

Peroxynitrite is probably the best candidate for triggering the DNA single-strand breakage and subsequent activation of PARS in inflammation. Another potential trigger is hydroxyl radical, which is known to contribute to the development of many inflammatory responses and is also capable of DNA single-strand breakage and poly(ADP-ribose) synthetase activation (Berger, 1985; Szabó, 1998). However, peroxynitrite (in contrast to hydroxyl radical) can travel significant distances from producer cell to target cell. Furthermore, NO can also travel significant distances and subsequently react with superoxide in the vicinity of cells, which then become subjected to peroxynitrite-mediated oxidant or nitrosative attack. Currently, in addition to peroxynitrite and hydroxyl radical, the only other trigger of DNA single-strand breakage that has been identified is NO⁻ (Ohshima *et al.*, 1998). Very little is known about the reactivity and production of this latter species *in vivo* (in

general) or in inflammation (in specific). Nevertheless, nitroxyl anion can be formed by the reaction of *S*-nitrosothiols with thiols (Wong *et al.*, 1998) or by the reaction of NO with superoxide dismutase (Murphy and Sies, 1991). Nitroxyl anion can also exert cytotoxic effects *in vitro* (Wink *et al.*, 1998). Nitroxyl anion induces cell necrosis, in some part, via PARS activation *in vitro* (C. Szabó, unpublished observation, 1999). Further work will be needed to determine whether NO⁻ is a new candidate capable of mediating DNA injury and PARS activation in inflammation.

PARS activation is important in peroxynitrite-induced cell necrosis, but it does not play a role as an effector pathway in NO⁻ or peroxynitrite-induced apoptosis. Inhibition of PARS does not prevent but, in some instances, increases peroxynitrite-induced apoptosis (Leist *et al.*, 1997; O'Connor *et al.*, 1997; Szabó *et al.*, 1997b; Virág *et al.*, 1998a). The mechanism of this enhanced oxidant-induced apoptosis in response to PARS inhibition is likely to be a consequence of the increased intracellular energetic stores (apoptosis being an energy-dependent process) (Virág *et al.*, 1998a–c).

PEROXYNITRITE-INDUCED INTERFERENCE WITH SIGNAL TRANSDUCTION

As previously discussed, NO, via *S*-nitrosylation reactions, can interrupt some signal transduction processes. Peroxynitrite-induced toxicity may also be related to the disruption of membrane signal transduction pathways. Multiple mechanisms of such interactions have been characterized (Gow *et al.*, 1996; Berlett *et al.*, 1996; Kong *et al.*, 1996; Elliott, 1996; Darley-Usmar and White, 1997). For example, phosphatidylinositol 3-kinase, a key enzyme involved in signal transduction cascades, has been shown to be nitrated by peroxynitrite, which results in an inhibition of its activity (Hellberg *et al.*, 1998). Peroxynitrite inhibits bradykinin-stimulated Ca²⁺ signaling in endothelial cells (Elliott, 1996). Peroxynitrite induced the nitration of both tyrosines of lymphocyte-specific tyrosine kinase, resulting in a complete inhibition of the catalytic activity of the enzyme (Kong *et al.*, 1996). In a more recent series of studies, exposure to peroxynitrite inhibited phosphoinositide hydrolysis activated by muscarinic or glutamatergic metabotropic receptors in cerebral cortical slices and in astrocytoma cells (De Sarno and Jope, 1998; Li *et al.*, 1998).

Membrane receptors can also be modified by peroxynitrite. An example is the epidermal growth factor receptor, which undergoes dimerization by peroxynitrite, probably involving intermolecular dityrosine cross-linking (Van der Vliet *et al.*, 1998a). In a study in erythrocytes, peroxynitrite induced a variety of alterations including (1) cross-linking of membrane proteins, (2) inhibition of band 3 tyrosine phosphorylation, (3) nitration of tyrosines in the 22K cytoplasmic domain of band 3, (4) binding of hemoglobin to the membrane, (5) irreversible inhibition of phosphotyrosine kinase activity, (6) massive methemoglobin production, and (7) irreversible inhibition of lactate production (Mallozzi *et al.*, 1997). Most of the evidence derives from reductionist experimental models. In addition, it is unclear whether the

concentrations or fluxes of peroxynitrite required for the induction of signal transduction disturbances are achieved during inflammation. Nevertheless, it is conceivable that peroxynitrite production *in vivo*, during inflammation, disturbs a variety of signal transduction mechanisms, which contributes to the pathophysiological actions of NO or peroxynitrite in inflammation.

PEROXYNITRITE-MEDIATED ACTIVATION OF CYCLOOXYGENASE

Following the original observation of Salvemini and colleagues in 1993, it was generally accepted that NO acts as an enhancer of the catalytic activity of cyclooxygenase (Salvemini *et al.*, 1993; Molina-Holgado *et al.*, 1995; Salvemini and Masferrer, 1996; Kanematsu *et al.*, 1997; Mollace *et al.*, 1998). This mechanism was found to serve both physiological or beneficial functions, as demonstrated in relation to the NO-mediated inhibition of platelet aggregation (Salvemini *et al.*, 1996a), and it has also been proposed to be of pathophysiological importance, as shown in models of renal inflammation (Salvemini *et al.*, 1994) and in systemic inflammation induced by LPS (Salvemini *et al.*, 1995). More recent studies in cultured, immunostimulated macrophages indicate that peroxynitrite, rather than NO, is responsible for the activation of cyclooxygenase (Landino *et al.*, 1996). It is probable that enhanced NO and/or peroxynitrite generation in inflammation can lead to increased prostaglandin formation, with all the usual consequences of prostaglandin formation in inflammation (pain, fever, swelling, etc.). The NO- or peroxynitrite-mediated activation of COX has been confirmed not only in prototypical reductionist animal models of inflammation (see later), but also in other pathophysiological conditions that are not considered inflammatory per se but have a significant inflammatory component, such as cerebral ischemia and reperfusion (Nogawa *et al.*, 1998).

It is noteworthy that, in addition to regulating the activity of cyclooxygenases, NO has been implicated in the transcriptional regulation of the expression of the inducible cyclooxygenase (COX-2). Inhibition of NOS in immunostimulated macrophages has been reported to suppress the expression of COX-2 (Habib *et al.*, 1997). It remains to be seen whether NOS inhibitors also exert an inhibitory effect on COX-2 expression in various forms of inflammation *in vivo*.

Pathophysiological Roles of Nitric Oxide in Inflammation

Toxic Vasodilation

Local overproduction of NO in the vicinity of blood vessels leads to local vasodilation in inflammation. Similarly, systemic overproduction of NO by the blood vessels in systemic inflammation (or shock) leads to extensive systemic vasodilation. The mechanism of this vasodilation involves a number of distinct mechanisms, which act in an additive or synergistic fashion. Excessive vasodilation (such as that

which occurs in various forms of systemic inflammation and shock) can be extremely detrimental, and it has been a target of many experimental therapeutic approaches involving various NOS inhibitor and NO scavenger compounds (Kilbourn *et al.*, 1997).

cGMP-DEPENDENT MECHANISMS OF NO-MEDIATED VASODILATION

As described earlier, many of the physiological actions of NO are mediated through the guanylyl cyclase/cGMP system. In an earlier line of research, Murad and colleagues studied the mechanism by which nitroglycerin and related nitrovasodilators elicit vascular smooth muscle relaxation. By 1977, it had been established that the mechanism by which these agents cause dilations involved NO-mediated activation of the soluble form of guanylyl cyclase, with a subsequent conversion of GTP to cyclic GMP (Katsuki *et al.*, 1977). The guanylyl cyclase–cGMP system turned out to be of central importance for mediating most of the physiological and some of the pathophysiological vascular actions of NO (Ignarro, 1991; Schmidt *et al.*, 1993). In this pathway, NO diffuses to adjacent cells and activates soluble guanylyl cyclase by binding to the iron on its heme component, thereby moving the iron out of the plane of the porphyrin ring. An increase in cytoplasmic cGMP, and the subsequent reduction of intracellular calcium concentration due to enhanced calcium extrusion and sequestration into intracellular stores (Twart and Van Breemen, 1988), was proposed to mediate the relaxation of vascular and nonvascular smooth muscle.

“Classic” inhibitors of guanylyl cyclase, such as methylene blue and hemoglobin, have been shown to improve vascular contractility in shock, and they cause an increase in the blood pressure of rodents subjected to endotoxin (Paya *et al.*, 1993). There were, however, some controversial issues regarding the specificity or nonspecificity of certain guanylyl cyclase inhibitors. For example, methylene blue is known to have additional pharmacological actions, including the generation of oxyradicals and direct inhibition of NOS (Marczin *et al.*, 1996). In more recent lines of investigation, a more specific and potent guanylyl cyclase inhibitor, which does not appear to have additional pharmacological actions, has been used (1*H*-[1,2,4]oxadiazolo[4,3-*a*]quinoxalin-1-one, or ODQ). This agent, too, inhibits the vasodilation induced by NO in intact vascular preparations, both when dilations are elicited by endothelium-dependent vasorelaxants and also when blood vessels are incubated with LPS for several hours in order to induce iNOS within the vasculature (Moro *et al.*, 1996).

cGMP-INDEPENDENT MECHANISMS OF VASODILATION

As mentioned earlier, it is now well established that NO (or a related species, such as peroxynitrite, see later) also has a number of cGMP-independent actions. The ability of NO to directly inhibit mitochondrial respiration within vascular smooth muscle cells is well established (Geng *et al.*, 1992). Moreover, NO generation has been shown to be associated

with DNA single-strand breakage in the vascular smooth muscle, which then activates PARS. Activation of this enzyme, in turn, leads to an ineffective DNA repair cycle, which depletes smooth muscle cells of their ATP and NAD stores and suppresses contractility during endotoxic shock (Szabó, 1998).

Part of the oxidant and cytotoxic effects of NO are due to reaction of NO with superoxide anion to form peroxynitrite, with subsequent formation of nitrogen dioxide and hydroxyl radical. The production of peroxynitrite is well established in various blood vessels and organs of animals subjected to endotoxic shock (Szabó *et al.*, 1995a; Szabó, 1996). Peroxynitrite can induce a number of other oxidant and cytotoxic processes, such as inhibition of the activity of membrane sodium–potassium antiport and inhibition of calcium pumps in the sarcoplasmic membrane (Viner *et al.*, 1996). It is conceivable that such effects would also impair the contractility of the vascular smooth muscle cells.

cGMP-independent activation by NO or peroxynitrite of other enzymes, such as COX, has also been described in various cell types (see earlier). Such an effect would be expected to increase the production of prostaglandins within the vascular smooth muscle. The finding that the cyclooxygenase inhibitor indomethacin further impaired rather than improved the contractility of the thoracic aortic rings obtained from endotoxin-treated rats (Wu *et al.*, 1994) suggests that, at least in this particular setting, the prostaglandins produced—possibly by NO-induced enhancement of the activity of COX—are predominantly vasoconstrictors. However, the vasoactive effects of the prostaglandins produced may well differ, depending on the species and the vascular bed.

Taken together, and contrary to the original suggestion that the NO-mediated progressive vasodilation is solely mediated by activation of guanylyl cyclase in the smooth muscle, it appears that there are multiple components of the NO-mediated vasodilation, especially under the conditions of local or systemic inflammation. These mechanisms may include metabolic mechanisms (inhibition of cellular energetics via multiple pathways), indirect actions of NO (via COX), and possibly also cGMP-independent activation of calcium-dependent potassium channels (Bolotina *et al.*, 1994; Pataricza *et al.*, 1995; Hall *et al.*, 1996) and ATP-sensitive potassium channels in the smooth muscle cell membrane (Murphy and Brayden, 1995). The relative importance of these pathways in the various stages and forms of inflammation and shock, and the interaction between these pathways, should be the subject of further investigations.

Role of Nitric Oxide or Peroxynitrite in the Development of Endothelial Dysfunction in Inflammation

There is a multitude of data demonstrating the impairment of the biosynthesis of NO from L-arginine by eNOS in the vascular endothelium in various forms of shock and inflammation (Szabó *et al.*, 1992a,b; Wang *et al.*, 1995). This

phenomenon is sometimes referred to as “isoform switch,” whereby the inducible isoform of NOS is expressed while the constitutive isoform of NOS is downregulated at the same time. Reduced production of NO from the endothelium would, in turn, enhance the adhesion and aggregation of platelets and the adhesion and activation of neutrophil granulocytes to the intima, thereby increasing the risk of multiple organ failure. Increased initial neutrophil adherence would, in turn, lead to further development of endothelial injury (via an oxyradical- or peroxynitrite-dependent mechanism) and would further exacerbate tissue injury. Interestingly, accumulating data suggest that, paradoxically, the development of endothelial dysfunction is dependent on NO. In a LPS-induced model of renal inflammation and dysfunction, selective inhibition of iNOS prevents the development of endothelial dysfunction (Swartz *et al.*, 1997). Similarly, in endotoxic shock, inhibition of iNOS protects against the development of endothelial dysfunction (Szabó *et al.*, 1996c; Fatehi-Hassanabad *et al.*, 1996). The mechanism of the NO-mediated endothelial dysfunction may be related to the generation of peroxynitrite in the vicinity of the endothelial cells and the activation of poly(ADP-ribose) synthetase in the vascular endothelium (Zingarelli *et al.*, 1997b; Szabó *et al.*, 1997b).

Role of Nitric Oxide in Inflammatory Pain Development

Pain development is a prototypical constituent of most inflammatory conditions. The mechanisms of pain development and sensation can be classified as peripheral and central mechanisms. The peripheral mechanism of hyperalgesia is considered to be the result of nociceptor sensitization. As potential agents involved in nociceptor sensitization, bradykinin, histamine, prostaglandins, protons, and nerve growth factor have been implicated (Mizumura, 1997; Mogil and Grisel, 1998). There is some evidence implicating a permissive role of basal NO production in prostaglandin E₂ (PGE)-induced hyperalgesia (Aley *et al.*, 1998). It appears that low levels of NO facilitate cAMP-dependent PGE₂-induced hyperalgesia, whereas higher levels of NO produce a cGMP-dependent hyperalgesia (Aley *et al.*, 1998). In another set of studies, the antinociceptive effects of peripherally applied κ - and δ -opioid agonists were found to be potentiated by the local action of NO, mainly via the cGMP pathway (Nozaki-Taguchi and Yamamoto, 1998). In animal models of arthritis, intraarticular injection of a non-isoform-selective NOS inhibitor resulted in a complete reversal of heat hyperalgesia (Lawand *et al.*, 1997). On the basis of these data, it is conceivable that inhibition of NO-mediated peripheral hyperalgesia and pain development may be an additional anti-inflammatory effect of NOS inhibitors. There is also some evidence for the involvement of NO in central pain sensing (Semos and Headley, 1994; Roche *et al.*, 1996). Interestingly, the antinociceptive effects of some drugs (e.g., ketorolac) can be suppressed by pharmacological inhibition of NOS (Ferreira, 1993; Granados-Soto *et al.*, 1995).

Role of Nitric Oxide in Inflammatory Plasma Extravasation

There is accumulating evidence for the involvement of NO, or a related species, in plasma extravasation associated with various forms of inflammation. Direct studies demonstrated that intradermally injected peroxynitrite acts, in a dose-dependent manner, to cause a marked increase in plasma extravasation (Greenacre *et al.*, 1997). Inhibition of NOS has been shown to suppress LPS-induced plasma leakage in the rat skin (Iuvone *et al.*, 1998). In addition, inhibition of iNOS activity with an aminoguanidine in the late phase of endotoxic shock attenuated plasma extravasation (Filep *et al.*, 1997). Furthermore, aminoguanidine abolished this LPS-induced enhancement of plasma leakage to substance P in the airways (Ohuchi *et al.*, 1998), and mercaptoethylguanidine attenuated the plasma extravasation in ligation-induced periodontitis (Lohinai *et al.*, 1998). The IL-2 induced pulmonary edema and pleural effusion is also partially iNOS dependent (Orucevic *et al.*, 1997). It is conceivable that inhibition of NO- or peroxynitrite-mediated plasma extravasation may be an additional anti-inflammatory mode of action of NOS inhibitors.

Regulation of Gene Expression by Nitric Oxide or Peroxynitrite: Relevance to Inflammation

Studies using various NOS inhibitors have been undertaken during the 1990s to unveil the consequences of NO production in inflammation. As described in previous sections, the sum of these observations appear to indicate that a basal level of NO, most likely provided by eNOS, has important organ-protective and anti-inflammatory effects. A second conclusion from these studies is that enhanced NO production during various forms of shock and inflammation frequently has detrimental consequences. In this scheme, iNOS is considered a terminal, final effector molecule of shock and inflammation. However, more recent work suggests that NO and peroxynitrite can also have signaling functions that might regulate gene expression and related cellular responses in shock and inflammation. In a model of hemorrhagic shock (a systemic inflammatory condition characterized by the production of proinflammatory cytokine and chemokine cascades, leukocyte adhesion molecule expression, and neutrophil infiltration into tissues), the lack of iNOS (selective pharmacological inhibition or genetic inactivation, i.e., with iNOS knockout mice) was associated with a marked reduction in the activation of NF κ B in the liver and lung as well as reductions in mRNA levels for IL-6 and granulocyte-colony stimulating factor (G-CSF) (Hierholzer *et al.*, 1998). Both IL-6 and G-CSF activate the transcription factor signal transducer and activator of transcription 3 (STAT3). Accordingly, STAT3 activation was reduced in the absence of iNOS activity. Occurring with these reductions in transcriptional factor activation and cytokine expression were a dramatic reduction in neutrophil infiltration into the lungs as well as reduced liver and lung injury measured by

plasma transaminase levels and wet-to-dry ratios, respectively (Hierholzer *et al.*, 1998). These studies indicated that NO can perform key signaling functions in hemorrhagic shock. With the many known targets for NO and peroxynitrite, this finding is perhaps not surprising. It is currently unclear whether this phenomenon is of general importance in inflammation and shock or, alternatively, it is specific to hemorrhagic shock. A relatively unique aspect of NO-mediated signaling in hemorrhagic shock is the associated redox stress. It is possible under conditions of reduced antioxidant capacity that NO or a reaction product such as peroxynitrite activates intracellular redox-sensitive signaling pathways.

A more general role of iNOS-derived NO (or peroxynitrite) as an amplifier of the inflammatory response is now also supported by the following observations: *in vitro*, inhibition of NOS can suppress the production of IL-1 (Vallette *et al.*, 1997), and peroxynitrite can stimulate the production of IL-8 in human whole blood via a mechanism that probably involves the activation of NF- κ B (Filep *et al.*, 1998; Cuthbertson *et al.*, 1998). Importantly, NO has been shown to mediate the cytokine-induced expression of matrix metalloproteinases (Sasaki *et al.*, 1998). In addition, peroxynitrite has been reported to directly enhance the activity of the neutrophil collagenase (Okamoto *et al.*, 1997). Both of these mechanisms may have important implications for the mechanism of the protective action of NOS inhibitors in arthritis. *In vivo*, inhibition of iNOS suppresses TNF production in allergic encephalomyelitis (Brenner *et al.*, 1997); inhibition of iNOS suppresses IL-1, collagenase, and stromelysin production in arthritis (Pelletier *et al.*, 1998; Brahn *et al.*, 1998); inhibition of iNOS suppresses IFN- γ production in a murine model of leishmaniasis (Diefenbach *et al.*, 1998); and the expression of a number of chemokines is suppressed in the absence of iNOS in zymosan-induced peritonitis (Ajuebor *et al.*, 1999). Taken together, this evidence paints an evolving picture of a pathway in which NO contributes to tissue damage both directly (in part, via the formation of peroxynitrite) and indirectly (i.e., through the amplification of the inflammatory response).

Mammalian Defense Mechanisms against the Actions of Nitric Oxide and Peroxynitrite in Inflammation

Both the microorganisms (which can be the target of iNOS-related NO or peroxynitrite production) and cells of the host organism (which, acting as "innocent bystanders," can be damaged in the inflammatory response) have developed multiple mechanisms for protection against NO- or peroxynitrite-related toxicities. Bacterial resistance to NO is not a subject of this chapter. Therefore, we only briefly mention here that in *Escherichia coli*, the SoxRS regulon was found to be required for resistance to redox-cycling agents that elevate cytosolic superoxide levels as well as for resistance to NO-dependent macrophage killing (Nunoshiba *et al.*, 1993, 1995). In contrast, in *Salmonella typhimurium*, SoxS is also required for enhanced expression of Mn-superoxide dismutase and resistance to paraquat, but not for resistance

to NO donor compounds, resistance to macrophage killing, or virulence in mice (Fang *et al.*, 1997). Additional studies demonstrated that bacterial resistance can be dependent on the inducible upregulation of the transcription factor oxy-R (Hausladen *et al.*, 1996) and NO dioxygenase (NOD), a microbial flavohemoglobin which oxidizes NO via a peroxynitrite-like intermediate, as demonstrated in *E. coli* (Gardner *et al.*, 1998b; Hausladen *et al.*, 1998). Periplasmic superoxide dismutase has also been shown to protect *Salmonella* from NO-mediated cytotoxicity (De Groote *et al.*, 1997). An additional defense mechanism in bacteria includes the subunit C of alkyl hydroperoxide reductase, an enzyme that reduces organic peroxides and that protects cells from reactive nitrogen intermediates, as demonstrated in *Mycobacterium tuberculosis* and *S. typhimurium* (Chen *et al.*, 1998).

The host organisms are defended against NO- or peroxynitrite-related toxicities by two main types of mechanisms: (1) scavengers/antioxidants and (2) regulated detoxifying pathways. There are a number of antioxidants in the cellular environment that can attenuate peroxynitrite-induced oxidative injury. In plasma, peroxynitrite oxidizes ascorbic acid, uric acid, tyrosine, and -SH groups of plasma proteins (Van Der Vliet *et al.*, 1994; Watts *et al.*, 1995). The reaction of peroxynitrite with thiols, which yields nitrosothiols and which may be the most important physiological detoxification mechanism of peroxynitrite, has been characterized only relatively recently. It appears to involve a direct nucleophilic nitrosation mechanism with elimination of hydroperoxyl anion (Van der Vliet *et al.*, 1998b). *In vitro* studies have established that endogenous scavengers of peroxynitrite include cysteine, glutathione, ascorbic acid, vitamin E, β -carotene, uric acid, and melatonin (Radi *et al.*, 1991; De Groot *et al.*, 1993; Van der Vliet *et al.*, 1994; Shi *et al.*, 1994; Hogg *et al.*, 1994; Pryor and Squadrito, 1995; Karoui *et al.*, 1996; Vatassery, 1996; Gilad *et al.*, 1997; Cuzzocrea *et al.*, 1997; Christen *et al.*, 1997). A marked depletion by exogenous or endogenous peroxynitrite of cellular antioxidants including glutathione has been reported in plasma as well as in various cell types, such as endothelial cells and smooth muscle cells (Van der Vliet *et al.*, 1994; Vatassery, 1996; Phelps *et al.*, 1995; Szabó *et al.*, 1996a). In the presence of plasma, proteins, glucose, or glutathione, peroxynitrite can form intermediates that act as NO donor compounds, as a form of a peroxynitrite-detoxifying mechanism (Moro *et al.*, 1994, 1995). There may be a delicate balance between peroxynitrite-mediated oxidant processes and endogenous antioxidant pathways that limit the reactivity of peroxynitrite.

The importance of endogenous glutathione in modulating peroxynitrite-related cytotoxicity is underlined by experiments using L-buthionine-(S,R)-sulfoximine (BSO), an inhibitor of γ -glutamylcysteine synthetase, which inhibits a key enzyme in the synthesis of glutathione, and thereby depletes intracellular glutathione. *In vitro* studies in neurons (Barker *et al.*, 1996), endothelial cells (Szabó *et al.*, 1997b; Cuzzocrea *et al.*, 1998a), and smooth muscle cells (Cuzzocrea *et al.*, 1998a) demonstrated a significant enhancement

of the peroxynitrite-induced suppression of mitochondrial respiration, DNA injury, tyrosine nitration, and protein oxidation by BSO pretreatment. On the other hand, exogenous glutathione and glutathione ethyl ester elicited protective effects against peroxynitrite-induced cytotoxicity (Barker *et al.*, 1996; Cuzzocrea *et al.*, 1998a). Similarly, in immunostimulated smooth muscle cells, depletion of glutathione enhances the degree of peroxynitrite-induced suppression of mitochondrial respiration, without affecting the amount of NO produced (Cuzzocrea *et al.*, 1998a). There is also a marked enhancement of protein oxidation in immunostimulated or peroxynitrite-challenged cells in the absence of glutathione (Cuzzocrea *et al.*, 1998a). The suppression of mitochondrial respiration in response to immunostimulation can be prevented by the NOS inhibitor *N*^G-methyl-L-arginine (L-NMA), confirming the role of NO or a related species, such as peroxynitrite, in the process (Cuzzocrea *et al.*, 1998a). These observations are of importance with respect to various forms of inflammation, shock, and ischemia-reperfusion injury. In several studies, depletion of endogenous glutathione pools has been shown to increase organ injury (Keller *et al.*, 1985; Nemeth and Boda, 1989; Stein *et al.*, 1990; P. Liu *et al.*, 1993). In shock, inflammation, and reperfusion injury, superoxide, hydroxyl radical, hydrogen peroxide, and peroxynitrite probably all contribute to the depletion of the endogenous antioxidant pool.

The relationship between antioxidant defenses and NO is complicated by the fact that NO and peroxynitrite have been shown to inactivate some of the antioxidant defenses of the mammalian cells. For example, glutathione reductase and glutathione-S-transferases have been shown to be inhibited by the NO carriers S-nitrosoglutathione and dinitrosyl-iron-complexed thiols (Asahi *et al.*, 1995, 1997; Keese *et al.*, 1997). Furthermore, peroxynitrite has been shown to inhibit superoxide dismutase (MacMillan-Crow *et al.*, 1996). Thus generation of toxic concentrations of NO or peroxynitrite in the cell can lead to attenuated defense systems or to even more oxidant formation via positive feedback cycles. For instance, exposure of mitochondria to peroxynitrite can lead to enhanced superoxide generation (Packer *et al.*, 1996), and exposure of thymocytes to an early, single burst of peroxynitrite induces a time-dependent reactive oxygen species generation (Virág *et al.*, 1998c). Neutralization of these secondary oxygen species with scavengers, in fact, can attenuate peroxynitrite-induced cell death (Virág *et al.*, 1998c).

With respect to transcriptionally regulated (inducible) eukaryotic defense mechanisms against NO, the available information is limited. Metallothionein, a major protein thiol induced in cells exposed to cytokines and bacterial products, has been shown to reduce the sensitivity of mammalian cells to NO donor compounds (Schwarz *et al.*, 1995). Heat-shock proteins have also been reported to be induced in response to exposure of mammalian cells to NO (Malyshev *et al.*, 1996; Hirvonen *et al.*, 1996; Byrne and Hanson, 1998). Furthermore, heat-shock protein expression or overexpression protects mammalian cells against NO- or peroxynitrite-mediated toxicity (Bellmann *et al.*, 1996; Szabó *et al.*,

1996d; Wong *et al.*, 1997a,b). It is unclear whether the mammalian cells, similar to the bacteria, can also express NOD-like or hemoglobin-like molecules, which would, in turn, protect against NO- or peroxynitrite-mediated toxicities. It is likely that inducible, multiple, regulated NO-detoxifying pathways exist in mammalian cells, and studies in this direction are expected to be a fruitful area of future research.

The Double-Edged Sword Dilemma: Nitric Oxide as Cytoprotector versus Cytotoxin

Under certain conditions, locally produced NO can exert marked antioxidant or cytoprotective actions, whereas in many other conditions, NO was found cytotoxic. This double-edged-sword-like role of NO has intrigued many investigators, but many details of the dual behavior of NO have yet to be clarified. Nevertheless, it is clear that, depending on the oxidative status of the cell and on a number of other conditions, NO can act as an antioxidant, neutralizing the cytotoxic actions of superoxide, whereas in other cases, NO enhances the cytotoxic potential of superoxide. The ratio of NO and superoxide has been implicated as a determinant of the apparent reactivity of peroxynitrite: excess NO reduces the oxidation elicited by peroxynitrite (Rubbo *et al.*, 1994; Villa *et al.*, 1994; Szabó *et al.*, 1995b; Miles *et al.*, 1996). Other cytoprotective mechanisms of NO are related to its reaction with caspases (via S-nitrosylation) and thereby inhibition of the apoptotic machinery (see earlier). The concentrations of NO required for this latter effect are relatively low, probably in the physiological range.

When considering the multifaceted roles of NO, it is not surprising that the pharmacological inhibition of the production of NO in inflammation may have either detrimental or protective effects. In general, NO produced by the constitutive endothelial NOS is considered protective: its inhibition exacerbates a number of forms of inflammation, mainly due to worsened tissue perfusion and increased neutrophil infiltration, platelet deposition, and microthrombus formation. This early NO production is essential in maintaining vascular patency in shock: its inhibition frequently worsens the outcome, whereas administration of NOS inhibitors in the late stage of shock is mostly protective (overviewed in Szabó, 1995; Kilbourn *et al.*, 1997). Nevertheless, eNOS-derived NO can also act as a cytotoxic species, for example, via its reaction with superoxide, in the early phase of reperfusion (see Szabó, 1996, for review).

The expression of iNOS can have beneficial effects, or deleterious effects, depending on the inflammatory condition in question. Factors that appear to dictate the consequences of iNOS expression include the type of insult, the tissue type, the level and duration of iNOS expression, and probably the redox status of the tissue. Overall, more attention has focused on the toxicity of iNOS. For example, induction of iNOS in endothelial cells produces endothelial injury (Palmer *et al.*, 1992). Induction of iNOS has been shown to inhibit cellular respiration in macrophages and vascular smooth muscle cells: these processes can lead to cell dys-

function and cell death (e.g., Ischiropoulos *et al.*, 1992b; Szabó *et al.*, 1996a,b,e, 1997e; Iwashina *et al.*, 1998). Such processes, when occurring within vascular smooth muscle cells, play a key role in the pathogenesis of the vascular hyporeactivity and progressive vascular decompensation associated with various forms of circulatory shock (see earlier). NO produced by iNOS also plays a role in the vasodilatory response associated with local inflammation (e.g., in the skin) (Iuvone *et al.*, 1998). In clear contrast, expression of iNOS in liver cells can suppress endotoxin and TNF- α -induced toxicity, by inhibition of caspase activation (Ou *et al.*, 1997; Kim *et al.*, 1998b). Overexpression of iNOS by gene transfer also limits LPS-induced toxicity in endothelial cells (Ceneviva *et al.*, 1998).

The role of iNOS may also well be dependent on the stage of the disease. For example, studies in experimental allergic encephalomyelitis have demonstrated that inhibition of iNOS expression in the early (induction) phase of the disease exacerbates the severity of the condition, whereas inhibition of iNOS in the late (inflammatory) phase of the condition has been shown to exert protective effects (Cross *et al.*, 1995; Brenner *et al.*, 1997; Okuda *et al.*, 1997; Sahrbacher *et al.*, 1998; Fenyk-Melody *et al.*, 1998).

Role of Nitric Oxide in Specific Inflammatory Conditions

Induction of iNOS and enhanced formation of NO have been demonstrated in almost all forms of inflammation, including arthritis (overviewed in Clancy *et al.*, 1998; Amin and Abramson, 1998; Stichtenoch and Frolich, 1998; Jang and Murrell, 1998), diabetes (Kolb-Bachofen, 1996; McDaniel *et al.*, 1996; Rothe and Kolb, 1999), systemic inflammatory response syndrome or circulatory shock (overviewed in Szabó, 1995; Kilbourn *et al.*, 1997), encephalomyelitis and other inflammatory conditions of the central nervous system (as overviewed in Kolb and Kolb-Bachofen, 1998; Hirsch *et al.*, 1998; Brosnan *et al.*, 1997; Parkinson *et al.*, 1997), colitis (Salzman, 1995; Alican and Kubes, 1996; Whittle, 1997; Guslandi, 1998), pancreatitis (Alhan *et al.*, 1998), gingivitis and periodontitis (Lohinai *et al.*, 1998), uveitis (Becquet *et al.*, 1997), transplant rejection (Cannon *et al.*, 1998; Disting and MacDonald, 1995), pneumonia (Akaike *et al.*, 1996), and myocarditis (Ishiyama *et al.*, 1997) among many others. The expression of iNOS has also been shown in many pathophysiological conditions that do not qualify as inflammation per se but do have a significant inflammatory component (e.g., atherosclerosis or the late phase of reperfusion injury) (e.g., Wildhirt *et al.*, 1995, 1996, 1997; Disting, 1996). In many of these conditions, the overproduction of NO, the expression of iNOS, the generation of peroxynitrite, and the protective effects of iNOS inhibition have been demonstrated.

As many of the inflammatory conditions listed are subjects of separate chapters in this book, detailed discussion on

the role of NO in the previously mentioned specific inflammatory conditions was not included in this chapter. However, we will discuss the findings related to NO in the pleurisy and paw edema models, because they are generally considered widely applicable, generic model systems for local inflammation. Furthermore, because of the general implications of the subject, we briefly contrast the results obtained with pharmacological inhibitors with the findings obtained with iNOS-deficient mice in various models of inflammation.

Pleurisy and Paw Edema Models

Carrageenan- and zymosan-induced paw edema and pleurisy models are widely considered (by pharmacologists working both in academia and in industry) convenient and rapid methods for the investigation of inflammatory responses. The cellular and molecular mechanisms of these inflammatory responses are well characterized, and these models of inflammation serve as standard models of screening for anti-inflammatory activity of various experimental compounds. The early phase of the inflammation is related to the production of histamine, leukotrienes, PAF, and possibly cyclooxygenase products, whereas the delayed phase of the inflammatory response has been linked to neutrophil infiltration and the production of neutrophil-derived free radicals, such as hydrogen peroxide, superoxide, and hydroxyl radical, as well as to the release of other neutrophil-derived mediators (Di Rosa *et al.*, 1971; Oh-Ishi *et al.*, 1989; Dawson *et al.*, 1991; Peskar *et al.*, 1991). These inflammatory conditions are associated with the expression of iNOS and overproduction of NO, which, after days, tend to return toward baseline or undetectable levels (Salvemini *et al.*, 1996b,c; Cuzzocrea *et al.*, 1997). There is also good evidence demonstrating that inhibition of NOS affects the course of the inflammation in these models. Both isoform-nonspecific and iNOS-selective inhibitors have been shown to be effective, although, as expected, the iNOS-selective agents only attenuate the delayed phase of the inflammation (Ialenti *et al.*, 1992; Fracasso *et al.*, 1996; Cuzzocrea *et al.*, 1998b). The protective effect of isoform-nonspecific agents may be due to local vasoconstriction, which, in this model, exerts anti-inflammatory effects (Medeiros *et al.*, 1995). Therefore, this model is in stark contrast with many of the pathophysiologically more relevant models of inflammation and shock, where eNOS has distinct protective actions, where inhibition of eNOS is crucial to preserve organ blood flow and function, especially in the early phase of the inflammation (see earlier), and where inhibition of eNOS usually exacerbates rather than reduces the development of inflammation.

Several of the cellular mechanisms of NO-mediated cytotoxicity outlined in the previous section have been identified in the pleurisy and paw edema models, including (1) a mechanism involving NO- or peroxynitrite-mediated activation of cyclooxygenase, (2) a role of peroxynitrite, and (3) the involvement of the PARS pathway. Regarding the role of NO-related activation of COX, endogenous NO has been

shown to modulate carrageenan-induced paw edema by increasing prostaglandin biosynthesis at the inflammatory site (Sautebin *et al.*, 1995; Demello *et al.*, 1997). However, in an air pouch model inflamed with zymosan, no evidence for the activation of COX by NO was found (Paya *et al.*, 1997).

Regarding peroxynitrite generation, a series of studies have demonstrated the production of peroxynitrite in these local models of inflammation (Salvemini *et al.*, 1996b,c; Cuzzocrea *et al.*, 1997, 1998b). Peroxynitrite has been directly shown to be able to cause an increase in both plasma extravasation and blood flow in the hind paw (Ridger *et al.*, 1997). In addition, using NOS inhibitors, superoxide dismutase mimetics, peroxynitrite decomposition catalysts, and other antioxidants, a connection between peroxynitrite generation and the inflammatory response has been put forward (Salvemini *et al.*, 1996b,c; Cuzzocrea *et al.*, 1997; Salvemini *et al.*, 1998).

Regarding PARS activation, studies have clearly demonstrated its role in various forms of local inflammation induced by the prototypical inflammatory stimuli zymosan and carrageenan. For example, in carrageenan-induced paw edema, inhibition of PARS with 3-aminobenzamide reduced paw swelling and inhibited the infiltration of neutrophils into the inflamed paw (Szabó *et al.*, 1997d). Furthermore, in a model of acute local inflammation (carrageenan-induced pleurisy) the poly(ADP-ribose) synthetase inhibitor 3-aminobenzamide inhibited the inflammatory response (pleural exudate formation, mononuclear cell infiltration, histological injury) (Cuzzocrea *et al.*, 1998b). Inhibition of PARS also reduced the formation of nitrotyrosine, an indicator of the formation of peroxynitrite, in the inflamed tissues (Szabó *et al.*, 1997d; Cuzzocrea *et al.*, 1998b). This finding is unexpected, because PARS activation is considered a process distal from the generation of oxidants. The explanation for this finding is likely related to the fact that the PARS^{-/-} phenotype or pharmacological inhibition of PARS reduces the infiltration of neutrophils into inflammatory sites (Szabó *et al.*, 1997d; Cuzzocrea *et al.*, 1998b). Thus, the reduction in tissue injury by PARS inhibitors may result from a decreased inflammatory infiltrate, which would be associated with a reduction in both oxygen- and nitrogen-centered free radical production. The basis for PARS-inhibitable neutrophil infiltration is not yet defined, but it may relate to the effect of PARS activation on the expression of intercellular adhesion molecules and/or may be due to modulation by PARS of a postadhesion event (Szabó *et al.*, 1997d; Zingarelli *et al.*, 1998b). Other mechanisms, such as a PARS-related effect on endothelial integrity, are also possible (Szabó *et al.*, 1997b).

Studies Using Inducible NO Synthase-Deficient Animals

As overviewed by Nathan (1997), in the few years following the generation of three lines of iNOS-deficient mice, a great number of pathophysiological studies were conducted using these animals as tools to provide a definitive answer to the question of the role of iNOS in inflammation.

Often, the findings using iNOS knockout animals were, however, found to be in conflict with some of the pharmacological data, and therefore the role of iNOS is still unclear (or, more likely, it is more complex than initially thought) in many forms of inflammation.

In the first set of studies, it was addressed whether the iNOS-deficient mice are resistant against LPS-induced hypotension, inflammation, shock, and lethality. Although anesthetized iNOS-deficient mice were protected against the LPS-induced hypotension and death (MacMicking *et al.*, 1995), no protection (or exacerbation) of the organ injury induced by *Corynebacterium parvum*/LPS shock was seen (MacMicking *et al.*, 1995). The next set of studies, in which the iNOS-deficient mice were completely resistant against LPS-induced death as opposed to wild types (50% death over 4 days) (Wei *et al.*, 1995), is frequently dismissed because of potential problems with genetic background differences between the wild-type and the iNOS-deficient groups of animals. In the study using the largest number of animals to date, no significant differences were found in survival rates in response to high doses of intraperitoneally injected LPS when wild types, heterozygotes, or iNOS knockout homozygotes were compared (Laubach *et al.*, 1995). Thus, the survival benefit that was expected on the basis of the studies with pharmacological inhibitors of NOS in murine models of shock could not be clearly demonstrated in the iNOS-deficient mice. It was, therefore, hypothesized that the pharmacological inhibitors of NOS may have had independent pharmacological effects in addition to NOS or iNOS inhibition, which may have affected the survival studies. Although this is a clear possibility, and it is known that guanidines, isothioureas, and even L-arginine analogs have pharmacological actions independent of NOS inhibition (Szabo *et al.*, 1994; Southan and Szabó, 1996), other considerations should also be kept in mind. For example, in many of the survival studies the NOS inhibitors were administered after the administration of the inducer of shock, whereas all iNOS-deficient studies are equivalent with a pharmacological prolonged “pretreatment” paradigm. Many investigators also assume that the iNOS-deficient animals, during development, may have expressed additional parallel cytotoxic pathways or mechanisms, which substitute for the absence of iNOS. In a study using iNOS-deficient mice, no parallel or alternative pathway was identified that would substitute for macrophage-mediated tumor cell lysis (Zingarelli *et al.*, 1998c). Nevertheless, a substantial degree of nitrotyrosine staining was identified in the iNOS-deficient animals after LPS injection, and thus evidence for significant, peroxynitrite-like oxidative processes was found in the absence of functional iNOS (Zingarelli *et al.*, 1998c). Thus, it is possible that in the absence of iNOS, NO produced by other NOS isoforms can combine with superoxide to result in the generation of peroxynitrite-like nitrosative species. More recent studies found that iNOS-deficient mice are resistant against LPS-induced pulmonary damage (Kristof *et al.*, 1998) and vascular hyporeactivity (Gunnnett *et al.*, 1998), confirming, in this respect, a multitude of prior studies using pharmaco-

logical inhibitors. In contrast to endotoxic shock, clear data have been presented demonstrating an improvement in the outcome of hemorrhagic shock in iNOS-deficient mice (Hierholzer *et al.*, 1998), in agreement with earlier studies using pharmacological inhibitors of NOS or agents that prevent the induction of iNOS (Thiemermann *et al.*, 1993b).

In allergic encephalomyelitis, iNOS plays opposing roles in the induction and the delayed phase of the disease: inhibition or inactivation of iNOS in the induction phase leads to the enhancement of the disease, whereas inhibition or inactivation of iNOS in the late phase has been found to be protective (Cross *et al.*, 1995; Zielasek *et al.*, 1995; Brenner *et al.*, 1997; Okuda *et al.*, 1997; Sahrbacher *et al.*, 1998; Fenyk-Melody *et al.*, 1998). Although iNOS appears to play opposing roles in the different stages of the disease, the degree of correlation between the pharmacological studies and the studies using iNOS-deficient animals appears to be fairly good.

The situation became more confusing when the studies on arthritis, uveitis, and glomerulonephritis with iNOS-deficient mice were completed. In a study using iNOS-deficient mice bred to the MRL-*lpr/lpr* mice (which, on normal background, develop autoimmune inflammatory pathologies associated with and apparently—based on pharmacological studies—due to iNOS expression), no protection against arthritis or glomerulonephritis was observed (although the vasculitis was reduced to some extent) (Gilkeson *et al.*, 1997). In a septic arthritis model even a significant exacerbation of the disease was found in the iNOS-deficient mice (McInnes *et al.*, 1998). These studies are in sharp contrast to the earlier pharmacological studies, where the development of arthritis has been shown to be ameliorated by various, nonisoform-selective inhibitors of NO synthase in various animal models of adjuvant- or collagen-induced arthritis (Ialenti *et al.*, 1992; McCartney-Francis *et al.*, 1994; Stefanovic-Racic *et al.*, 1993, 1994, 1995; Evans *et al.*, 1995; Weinberg *et al.*, 1994; Connor *et al.*, 1995; Fletcher *et al.*, 1998; Brahn *et al.*, 1998; Pelletier *et al.*, 1998). In one study, however, zymosan-induced gonarthritis has been shown to be reduced in the iNOS-deficient mice (Van de Loo *et al.*, 1998). It remains to be determined whether (similar to the case of allergic encephalomyelitis) iNOS plays different roles in the early and delayed phase of arthritis and in other forms of inflammation.

No protection against uveitis can be found in the iNOS-deficient mice (F. R. Smith *et al.*, 1998). Again, this is in sharp contrast to many previous pharmacological studies (Goureau *et al.*, 1994; Parks *et al.*, 1994).

Emerging studies using iNOS-deficient mice have clarified that the expression of iNOS appears to have diverse roles in the various stages of transplant rejection: NO from iNOS appears to prevent acute rejection but promotes chronic rejection (Koglin *et al.*, 1998a). Transplant-induced atherosclerosis is enhanced in the absence of iNOS (Koglin *et al.*, 1998b). iNOS has also been linked to ischemia-reperfusion mediated injury: renal proximal tubules are resistant against hypoxia-induced injury in the absence of functional

iNOS gene (Ling *et al.*, 1998), and the iNOS-deficient mice perform better in the delayed phase of stroke (Iadecola *et al.*, 1997).

Conclusions

The pathophysiological roles of NO in inflammation are far from being simple, uniform, or well understood. NO produced from iNOS may play different roles in various pathophysiological conditions. Moreover, NO plays different, sometime opposing roles in different stages of the same disease. In many cases, for example, in conditions of viral infection and inflammation, the anti-inflammatory effect of NOS inhibition is masked by attenuation of the host defense mechanisms (Karupiah *et al.*, 1993, 1998). Currently, no clinical data are available with selective inhibitors of iNOS. The only clinical study using a NOS inhibitor (N^G -methylarginine in sepsis) failed in Phase III, most likely due to unacceptable side effects related to inhibition of constitutive NO production. Clinical studies with appropriate iNOS inhibitors, in carefully selected inflammatory conditions, will clarify the ultimate pathogenetic role of iNOS in the human inflammatory conditions.

RHEUMATOID ARTHRITIS (RA) IS A CHRONIC SYSTEMIC DISEASE OF UNKNOWN ETIOLOGY CHARACTERIZED BY SYMMETRIC POLYARTICULAR INFLAMMATION OF SYNOVIA-LINED JOINTS, REMARKABLE JOINT SWELLING, DEFORMATION, AND PAIN. INDEED, CHRONIC PAIN IS ONE OF THE MOST SERIOUS SYMPTOMS ASSOCIATED WITH RA AND AFFECTS THE QUALITY OF LIFE OF RA PATIENTS. PROMINENT HISTOPATHOLOGICAL FEATURES OF THE CHRONICALLY INFLAMED SYNOVIA INCLUDE NEOVASCULARIZATION, HYPEREMIA, INFILTRATION OF LARGE NUMBERS OF LEUKOCYTES, AND BONE AND CARTILAGE DEGRADATION. COINCIDENT WITH THIS EXTENSIVE INFLAMMATORY INFILTRATE IS THE ENHANCED EXPRESSION OF THE INDUCIBLE ISOFORM OF NITRIC OXIDE SYNTHASE (iNOS) AND THE SUSTAINED OVERPRODUCTION OF THE FREE RADICAL NITRIC OXIDE (NO). BECAUSE NO IS KNOWN TO DIRECTLY OR INDIRECTLY MODULATE THE INFLAMMATORY RESPONSE AS WELL AS TO PLAY AN IMPORTANT ROLE IN PAIN PERCEPTION (HYPERALGESIA), THERE IS INCREASING INTEREST IN DEFINING THE ROLE THAT NO MAY PLAY IN THE PATHOGENESIS OF RA AND CHRONIC PAIN. THE OBJECTIVE OF THIS CHAPTER IS TO REVIEW SOME BASIC CONCEPTS OF NO BIOLOGY THAT MAY HELP IN UNDERSTANDING THE ROLE THAT NO MAY PLAY IN THE PATHOPHYSIOLOGY OF CHRONIC JOINT INFLAMMATION AND PAIN PERCEPTION.

Introduction

Rheumatoid arthritis (RA) is a chronic systemic disease of unknown etiology characterized by symmetric polyarticular inflammation of synovia-lined joints and progressive loss of articular cartilage and subchondral bone (Firestein, 1998). Corresponding to these pathophysiological events is remarkable joint swelling, deformation, and pain. The healthy joint is normally encapsulated by a thin, four- to five-cell-thick synovial membrane (Fig. 1). Chronic inflammation of this membrane initiates a cascade of molecular and cellular events that culminate in hyperplasia of the synovial membrane, resulting in the formation of an invasive, tumor-like extension of the synovial membrane called pannus (Fig.

1). It is thought that pannus-derived hydrolytic enzymes (e.g., metalloproteinases) are responsible for the cartilage and bone degradation observed in RA (Firestein, 1998). Other studies have demonstrated that angiogenesis may be crucial for the development of pannus in RA (Koch, 1998).

Other prominent pathological features of the chronically inflamed synovia include neovascularization, hyperemia, and the infiltration of large numbers of leukocytes. Indeed, one of the hallmark features of RA is the infiltration of large numbers of mononuclear leukocytes (monocytes, plasma cells, and lymphocytes) into the inflamed synovia. Interestingly, extensive polymorphonuclear leukocyte (PMN) extravasation is observed in synovial fluid but not in inflamed synovial tissue. Because this inflammatory infiltrate is

Figure 1 Schematic representation of the normal and chronically inflamed synovia.

accompanied by extensive articular damage including cartilage and bone erosion, edema, and enhanced vascular permeability, it has been suggested that these leukocytes play an important role in initiating and perpetuating the synovitis as well as cartilage and bone degradation observed in RA (Firestein, 1998; Koch, 1998).

Studies have demonstrated that the enhanced leukocyte infiltrate and some of the pathophysiology observed in different models of synovitis and in human RA may be mediated by the interaction between leukocytes and specific endothelial cell adhesion molecules (ECAMs) (Issekutz and Issekutz, 1995; Issekutz *et al.*, 1996, 1996; Kavanaugh *et al.*, 1994, 1996, 1997; Schimmer *et al.*, 1997). In addition to promoting adhesion and extravasation of potentially damaging leukocytes into the synovia, certain ECAMs such as P- and L-selectin have been shown to play an important role in mediating the recruitment of β -endorphin-containing, memory-type T lymphocytes into inflamed sites (Machelska *et al.*, 1998). Thus, these types of leukocyte-endothelial cell interactions may be important in controlling inflammatory pain. Coincident with this extensive inflammatory infiltrate is the enhanced expression of the inducible isoform of nitric oxide synthase (iNOS) and the sustained overproduction of the free radical nitric oxide (NO) (Clancy *et al.*, 1998; Cochran *et al.*, 1996; Evans *et al.*, 1995; Jang and Murrell, 1998; Stichtenoth and Frolich, 1998). Because NO is known to directly or indirectly modulate the inflammatory response as well as play an important role in pain perception (hyperalgesia), there is increasing interest in defining the role that NO may play in the pathogenesis of RA and chronic pain. This chapter will review some basic concepts of NO biology

that may help in understanding the role that NO may play in the pathophysiology of chronic joint inflammation and pain perception.

Role of Cytokines in the Pathogenesis of Rheumatoid Arthritis

Although the etiology of RA remains undefined, it is thought that the initiation and pathogenesis of this disease is multifactorial, involving interactions among genetic, immune, and possibly infectious agents (Firestein, 1998; Weyand and Goronzy, 1997). Indeed, there is a growing body of experimental and clinical evidence to suggest an immune-mediated pathogenesis of RA.

The first step in the immune response to antigen is the uptake, processing, and presentation of antigen by macrophages and/or other antigen presenting cells (Fig. 2). Antigen recognition by T lymphocytes activates these cells to synthesize and release interleukin 2 (IL-2) and γ -interferon (IFN- γ). IL-2 promotes the clonal expansion of cytotoxic T cells and enhances the function of helper T cells and B cells, whereas IFN- γ interacts with and activates antigen presenting cells and macrophages to produce IL-12 (Trinchieri, 1998). IL-12 feeds back onto the T cells to enhance further production of IFN- γ . IFN- γ can then activate endothelial cells and enhance ECAM expression on endothelial cells. Interferon-activated macrophages produce large amounts of T-helper cell-1 (Th1)-type cytokines such as tumor necrosis factor α (TNF- α), IL-1, IL-6, IL-8, and IL-12 as well as reactive oxygen metabolites, all of which are thought to be important in initiating and/or promoting the inflammatory response via promotion of angiogenesis and pannus growth as well as recruitment and activation of PMNs and macrophages. Indeed, RA is thought to be associated with an imbalance in cytokine formation resulting in the overproduction of Th1-type or proinflammatory cytokines (Odeh, 1997; Schulze-Koops *et al.*, 1995) (Fig. 3).

The importance of cytokines as mediators of chronic joint inflammation can be seen in clinical studies where investigators have demonstrated that administration of IL-1 receptor antagonist or antibodies specific for Th1-derived cytokines such as TNF- α attenuate the chronic joint inflammation observed in different animal models of synovitis as well as human RA (Elliott *et al.*, 1994; Lebsack *et al.*, 1991). In addition, Th1-type cytokines are also known to upregulate the expression of iNOS, resulting in enhanced production of NO (Clancy *et al.*, 1998; Cochran *et al.*, 1996; Evans *et al.*, 1995; Jang and Murrell, 1998; Stichtenoth and Frolich, 1998). It is interesting to note that some of the dramatic anti-inflammatory activity demonstrated in clinical studies using the anti-TNF monoclonal antibody (cA2) is associated with a reduction in expression of iNOS in patients with RA (Perkins *et al.*, 1998). The role that iNOS-derived NO plays in modulating joint inflammation is currently under active investigation, the results of which are not entirely clear. An

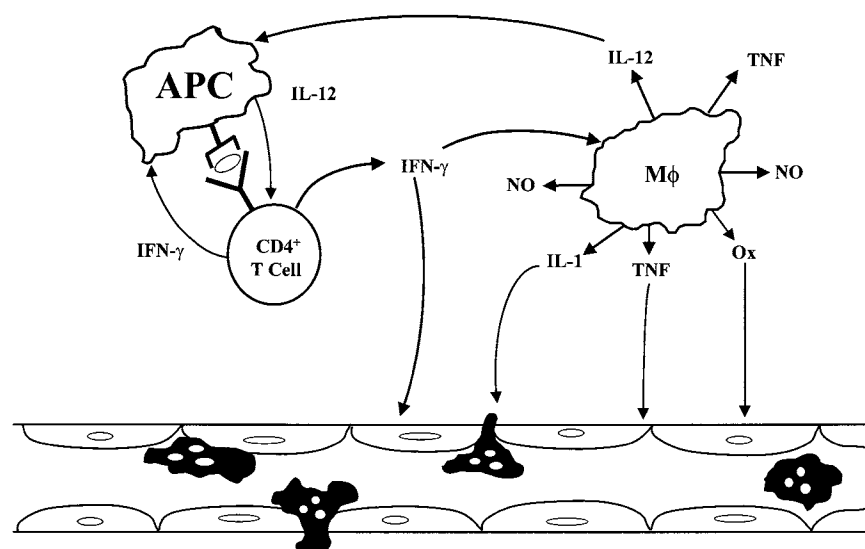

Figure 2 Interaction between antigen presenting cell (APC) and CD4⁺ T lymphocytes to produce cytokines. Ox represents reactive oxygen species such as superoxide and hydrogen peroxide, and Mφ stands for macrophage.

understanding of some of the basic concepts involved in regulation of the inflammatory response may prove useful in ultimately defining the role of NO in the pathophysiology of RA.

Regulation of Chronic Joint Inflammation

It has been appreciated for some time that chronic joint inflammation is associated with increased production of reactive oxygen metabolites such as superoxide (O_2^-), hydrogen peroxide (H_2O_2), and possibly hydroxyl radical ($HO\cdot$) (Biernacki *et al.*, 1984; Blake *et al.*, 1990; Chapman *et al.*,

1989; Clancy *et al.*, 1998; Cochran *et al.*, 1996; Dabbagh *et al.*, 1991; Edwards *et al.*, 1988; Evans *et al.*, 1995; Halliwell, 1995; Jang and Murrell, 1998; Shingu *et al.*, 1994; Skaleric *et al.*, 1991; Stichtenoth and Frolich, 1998). Historically, it has been thought that these oxidants and free radicals promote synovitis as well as bone and cartilage damage directly via their ability to degrade important cellular constituents and biopolymers such as hyaluronic acid proteoglycans and collagen (Halliwell, 1995).

More recent data suggests that reactive oxygen species may also initiate and/or perpetuate chronic joint inflammation by activating the transcription of a variety of different

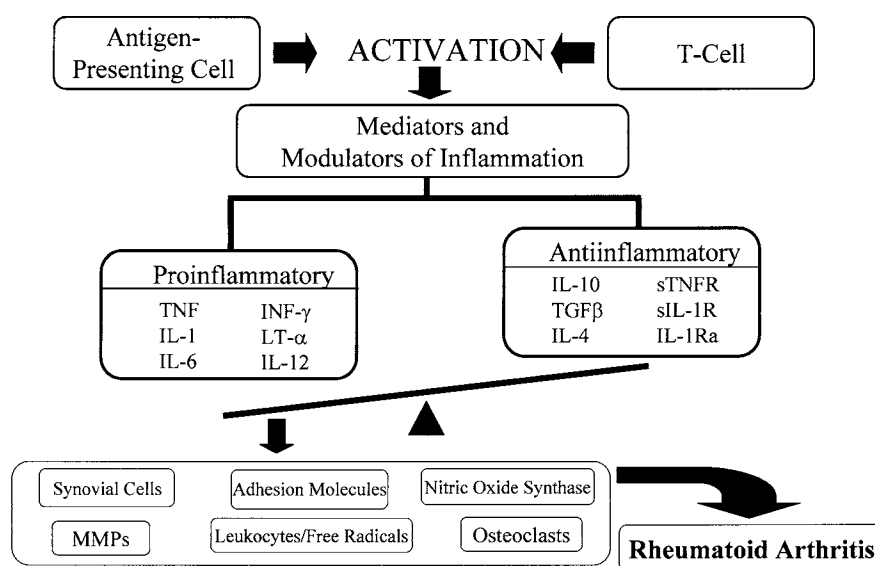

Figure 3 Proposed cytokine imbalance produced by immune cell activation in rheumatoid arthritis. MMPs represent matrix metalloproteinases, whereas sTNFR, sIL-1R, and IL-1Ra represent soluble TNF receptor, soluble IL-1 receptor, and IL-1 receptor antagonist, respectively.

genes known to be important in the inflammatory response. For example, certain reactive oxygen species are known to activate specific transcription factors such as nuclear transcription factor κ B (NF- κ B). It is well appreciated that Th1-derived cytokines such as TNF- α , TGF- β (lymphotoxin- α), and IFN- γ either alone or in combination promote leukocyte adhesion *in vitro* and *in vivo* as well as upregulate the expression of iNOS (Baeuerle and Henkle, 1994; Xie *et al.*, 1994). The mechanisms by which this diverse group of proinflammatory agents promote leukocyte adhesion and enhance NO production *in vivo* are not clear; however, recent *in vitro* data suggest that cytokine-receptor interaction may activate NF- κ B. This heterodimeric protein is a ubiquitous transcription factor and pleiotropic regulator of numerous inflammatory and immune responses. Once activated, NF- κ B translocates to the nucleus of the cell where it binds to its consensus sequence on the promoter-enhancer region of different genes, thereby activating the transcription of genes known to be important in the immune and inflammatory responses (Baeuerle and Henkle, 1994). For example, NF- κ B appears to regulate the transcription of a variety of different cytokines (e.g., IL-1, IL-2, TNF, IL-6, IL-8), certain ECAMs such as intracellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), E-selectin, and mu-

cosal addressin cell adhesion molecule-1 (MAdCAM-1), as well as iNOS (Baeuerle and Henkle, 1994; Collins *et al.*, 1995; Palombella *et al.*, 1998; Read *et al.*, 1995; Xie *et al.*, 1994). Thus, NF- κ B may regulate inflammation directly or indirectly via its ability to activate the transcription of inflammatory cytokines.

NF- κ B belongs to the Rel family of transcription factors (Baeuerle and Henkle, 1994), whose members share a region of about 300 amino acids known as the Rel homology domain. The heterodimeric NF- κ B is composed of p50 and p65 subunits and is normally sequestered in the cytoplasm in association with its inhibitor I κ B (Baeuerle and Baltimore, 1995). A large number of different bacterial and viral products, cytokines, and lipid mediators activate NF- κ B (Baeuerle and Henkle, 1994). It is unlikely that each of these stimuli activates the cytoplasmic NF- κ B-I κ B complex via completely different pathways. Indeed, there is a growing body of experimental data to suggest that many, if not all, of these stimuli activate multiple signaling pathways that converge to enhance reactive oxygen metabolism within the cell (Fig. 4) (Schmidt *et al.*, 1995; Schreck *et al.*, 1991, 1992a,b; Sen and Packer, 1996). This has been shown for the NF- κ B activators TNF, IL-1, lipopolysaccharide, phorbol esters, UV light, γ radiation, anti-immunoglobulin M (IgM), okadaic

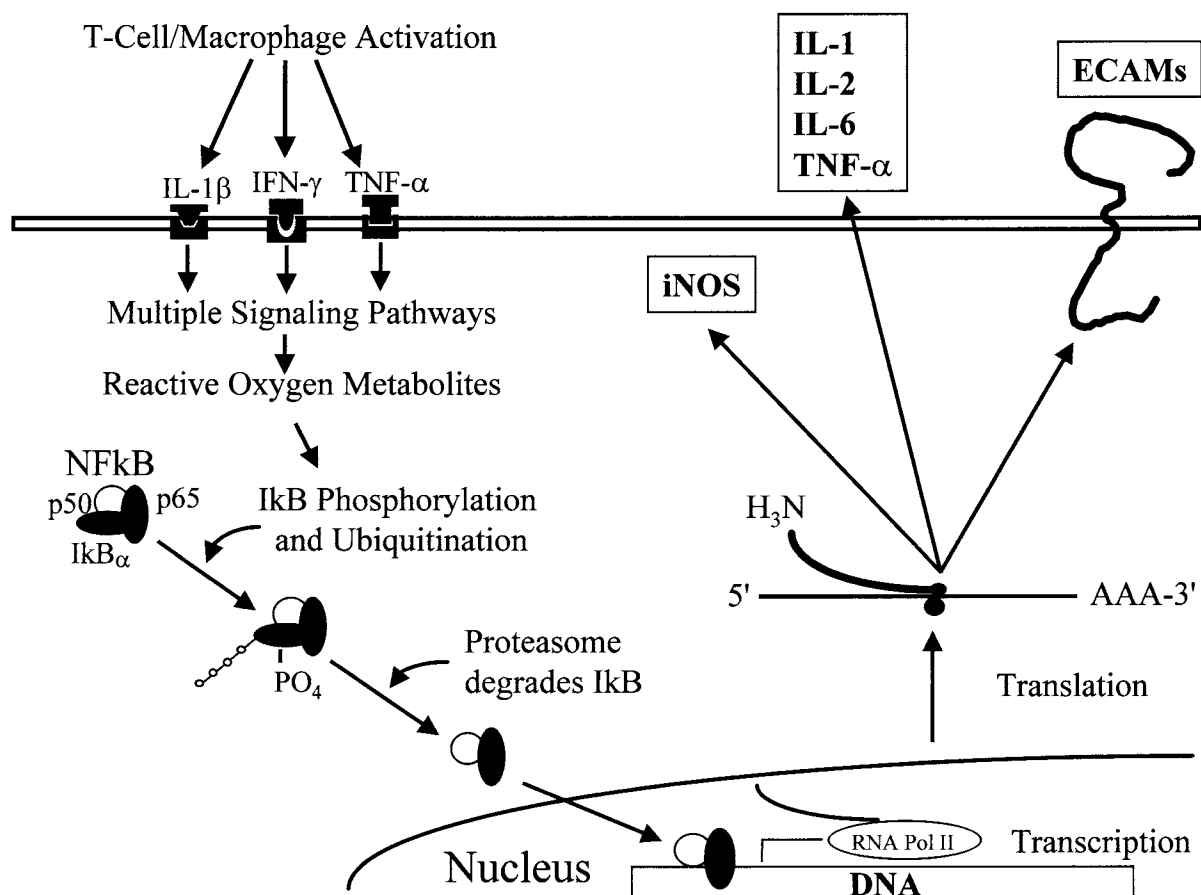

Figure 4 Role of cytokines, reactive oxygen species, and the 26S proteasome in the activation and translocation of nuclear factor κ B (NF- κ B).

acid, and anti-CD28. Further support for this concept is the recognition that certain lipophilic, membrane-permeable oxidants, such as H_2O_2 and oxidant-producing xenobiotics (e.g., menadione), active NF- κ B as well (Sen and Packer, 1996).

The specific intracellular source(s) for this enhanced oxidative metabolism has not been identified, but prostaglandin synthase, xanthine oxidase, mitochondria, NADPH oxidase, and cytochrome P-450 are likely candidates (Munroe *et al.*, 1995; Schulze-Osthoff *et al.*, 1993; Suzuki *et al.*, 1992; Weber *et al.*, 1994). Sources of exogenous oxidants *in vivo* that could activate NF- κ B include activated phagocytic leukocytes (e.g., PMNs, monocytes, macrophages, eosinophils). Furthermore, NF- κ B activation has been shown to be inhibited *in vitro* by a wide variety of structurally diverse enzymatic or nonenzymatic antioxidants or free radical scavengers such as superoxide dismutase (SOD), catalase, glutathione (GSH) peroxidase, *N*-acetylcysteine, vitamin E derivatives, α -lipoic acid, and certain dithiocarbamates (reviewed in Schmidt *et al.*, 1995; Schreck *et al.*, 1991, 1992a,b; Sen and Packer, 1996). Furthermore, two studies have demonstrated that certain antioxidants inhibit NF- κ B *in vivo* and protect the lung from inflammatory tissue injury (Blackwell *et al.*, 1996; Ye and Malik, 1997). Indeed, it is intriguing to speculate that the observed protective effects of antioxidants in various models of RA (Shingu *et al.*, 1994; Skaleric *et al.*, 1991) may be due more to inhibition of NF- κ B activation than inhibition of oxidant-induced toxicity. One study demonstrated activation and nuclear translocation of NF- κ B in synovia obtained from patients with RA (Handel *et al.*, 1995).

The mechanisms by which oxidants activate NF- κ B have not been defined. This intracellular oxidative stress is thought to then activate, via several intermediate reactions, one or more redox-sensitive kinases that specifically phosphorylate I κ B (Mercurio *et al.*, 1997; Woronicz *et al.*, 1997) (Fig. 4). Once phosphorylated, I κ B is selectively ubiquitinated and then degraded via the nonlysosomal, ATP-dependent 26S proteolytic complex (Goldberg, 1995; Palombella *et al.*, 1994). Thus, the 26S proteasome represents an important step in the activation of NF- κ B (Fig. 4).

Because the proteolytic degradation of the posttranslationally modified I κ B is known to be mediated by the 26S proteasome complex, the therapeutic anti-inflammatory activity of a selective proteasome inhibitor in a model of chronic polyarthritis was assessed (Palombella *et al.*, 1998). Chronic polyarthritis with granulomatous liver inflammation was induced in female Lewis rats via the intraperitoneal injection of peptidoglycan polysaccharide (PG/PS). Twenty-one rats were randomized into three groups consisting of a saline-injected control group, a PG/PS arthritic group given vehicle (methylcellulose) orally (p.o.) daily beginning 7 days following the induction of arthritis, and a PG/PS arthritic group given $0.3 \text{ mg kg}^{-1} \text{ day}^{-1}$ PS-341 (proteasome inhibitor; $K_i = 0.6 \text{ nM}$) p.o. daily beginning 7 days following the induction of arthritis and continuing daily for an additional 3 weeks. Arthritic symptoms were monitored throughout the course of the study and were quantified using the

total arthritis index score and measurement of paw volume. PS-341 was found to attenuate polyarthritis induced by the intraperitoneal injection of PG/PS as assessed by significant reductions in the total arthritis and average hind paw volume (Palombella *et al.*, 1998). Histologically, drug treatment attenuated the cellular infiltration, synovial thickening, and pannus formation as well as the bone and cartilage erosion typical of PG/PS-induced arthritis. This inhibition of polyarthritis correlated with significant reductions in plasma levels of nitrate and nitrite and IL-6 compared to vehicle-treated controls. The gross liver inflammation score was also attenuated by drug treatment. Furthermore, PG/PS-induced upregulation of liver inducible nitric oxide synthase and VCAM-1 expression were significantly attenuated by therapeutic treatment with PS-341 (Palombella *et al.*, 1998). It was concluded that the 26S proteasome and thus NF- κ B play important roles in regulating the acute and chronic inflammation responses *in vivo*. These data also suggest that the antiadhesive and anti-inflammatory properties of antioxidants, free radical scavengers, and proteasome inhibitors may be due to their abilities to inhibit the activation of NF- κ B and the subsequent upregulation of ECAM expression on the endothelium.

Although it is tempting to conclude that inhibition of NF- κ B activation attenuates joint inflammation via the pathways described, it should be remembered that chronic NF- κ B inhibition also results in apoptosis (see Grisham, 1999, and references therein). Some of the anti-inflammatory activity observed using PS-341 may in fact be due to selective apoptosis of microvascular endothelial cells and/or pannus.

Role of Nitric Oxide as an Endogenous Modulator of Joint Inflammation

One of the most consistent findings in experimental or human RA is the large and significant overproduction of NO in the inflamed joint (Clancy *et al.*, 1998; Cochran *et al.*, 1996; Evans *et al.*, 1995; Issekutz *et al.*, 1996; Issekutz and Issekutz, 1995; Jang and Murrell, 1998; Kavanaugh *et al.*, 1994, 1996, 1997; Koch, 1998; Schimmer *et al.*, 1997; Stichetenoth and Frolich, 1998). From a physiological perspective, NO is a particularly interesting bimolecular species in that it possesses both anti-inflammatory as well as proinflammatory properties (Table I). For example, exogenous NO donor agents have been shown to attenuate the adhesion and recruitment of leukocytes in postcapillary venules exposed to a variety of different acute inflammatory stimuli (Gaboury *et al.*, 1993; Kurose *et al.*, 1994; Liao and Granger, 1995).

One explanation that has been offered to explain the antiadhesion properties of NO relates to the ability of this molecule to rapidly interact with and decompose O_2^- (Gaboury *et al.*, 1993). Since O_2^- reacts with NO three times faster than with superoxide dismutase (Huie and Padmaja, 1993), it has been proposed that NO may act as a physiological scavenger of O_2^- . However, depending on the relative fluxes

Table I Modulatory Role of Nitric Oxide in Chronic Joint Inflammation^a

Anti-inflammatory properties	Proinflammatory properties
Inhibits leukocyte–endothelial cell adhesion and extravasation	Acts as vasodilator (increases blood flow)
Inhibits metal-catalyzed oxidative reactions	Enhances vascular permeability
Inhibits ECAM expression	Induces TNF- α synthesis
Inhibits lymphocyte proliferation	Stimulates metalloproteinases
Inhibits platelet aggregation	Inhibits proteoglycan and collagen synthesis
	Inhibits actin polymerization and integrin signaling
	Induces chondrocyte apoptosis
	Downregulates IL-1 receptor antagonist receptor expression
	Increases susceptibility of cells to oxidant injury
	Inhibits mitochondrial respiration
	Inhibits DNA synthesis
	Increases bone resorption

^aDerived from Clancy *et al.* (1998), Cochran *et al.* (1996), Evans *et al.* (1995), and Jang and Murrell (1998), Koch (1998), and Stichtenoth and Frolich (1998).

of each radical, NO may inhibit or enhance oxidant production via the degradation or synthesis of peroxynitrite (ONOO⁻) (Grisham *et al.*, 1999). This possibility is supported by studies demonstrating that NO donor compounds are only effective in inhibiting leukocyte–endothelial cell adhesion in models of inflammation in which SOD is also antiadhesive (Gaboury *et al.*, 1993; Kurose *et al.*, 1994).

A second mechanism by which NO may attenuate leukocyte adhesion during the acute inflammatory response involves modulation of ECAM expression. It has been shown that NO donor compounds prevent the mobilization of preformed P-selectin that is observed within 30 min after reperfusion of the ischemic intestine (Gauthier *et al.*, 1994). Furthermore, it has been shown that exogenous NO donor compounds induce the expression of and/or stabilize I κ B, thereby maintaining NF- κ B in its inactive form bound to I κ B (DeCaterina *et al.*, 1995; Khan *et al.*, 1996; Peng *et al.*, 1995). Although this mechanism has been proposed to account for the ability of NO to attenuate surface expression of certain ECAMs on human endothelial cells *in vitro*, we have been unable to demonstrate this anti-inflammatory effect of NO on ECAM expression in models of chronic inflammation *in vivo* where both ECAMs and iNOS are coexpressed (Kawachi *et al.*, 1999).

Although several studies have demonstrated potent antiadhesive activity of NO *in vitro* and in acute inflammation *in vivo*, the role of NO in chronic joint inflammation is far from clear-cut. In fact, numerous studies have indicated that chronic joint inflammation may be attenuated by administration of a variety of NOS inhibitors, indicating that NO may directly or indirectly promote rather than inhibit chronic inflammation (Conner *et al.*, 1995; Fletcher *et al.*, 1998; Gilkeson *et al.*, 1997; Ialenti *et al.*, 1993; Lawand *et al.*, 1997; McCartney-Francis *et al.*, 1993; McInnes *et al.*, 1998; Oyanagui *et al.*, 1994; Pozza *et al.*, 1998; Sakiniene *et al.*, 1997; Salvemini *et al.*, 1996; Santos *et al.*, 1997; Stefanovic-Racic

et al., 1994, 1995; Van de Loo *et al.*, 1998; Verissimo de Mello *et al.*, 1997; Weinberg *et al.*, 1994) (Table II). The mechanisms by which the sustained overproduction of iNOS-derived NO promotes chronic joint inflammation, or more precisely the mechanisms by which NOS inhibitors attenuate experimental RA, have not been clearly delineated; however, there are several possibilities (Table II). For example, chondrocyte, macrophage, and synovial fibroblasts are thought to produce large amounts of NO within the inflamed synovia (Clancy *et al.*, 1998; Cochran *et al.*, 1996; Evans *et al.*, 1995; Issekutz *et al.*, 1996; Issekutz and Issekutz, 1995; Jang and Murrell, 1998; Kavanaugh *et al.*, 1994, 1996, 1997; Koch, 1998; Schimmer *et al.*, 1997; Stichtenoth and Frolich, 1998).

The sustained overproduction of NO could contribute to the pathophysiology of RA by several mechanisms. First, NO has been implicated in the enhanced microvascular permeability induced by IL-2 (Clancy *et al.*, 1998; Cochran *et al.*, 1996; Evans *et al.*, 1995; Jang and Murrell, 1998; Koch, 1998; Stichtenoth and Frolich, 1998). Increases in vascular permeability could account for the edema and swelling observed during acute flares of RA. Second, a substantial number of studies have demonstrated some rather dramatic effects of NO on chondrocyte function. For example, enhanced production of NO has been shown to (a) stimulate metalloproteinase activity, (b) inhibit proteoglycan and collagen synthesis, (c) inhibit actin polymerization and β 1 integrin signaling, (d) enhance susceptibility to reactive oxygen-induced cytotoxicity, (e) decrease expression of IL-1 receptor antagonist, and (f) induce apoptosis (Clancy *et al.*, 1998; Cochran *et al.*, 1996; Evans *et al.*, 1995; Jang and Murrell, 1998; Koch, 1998; Stichtenoth and Frolich, 1998). In addition, NO may enhance bone resorption and inhibit osteoblast function (Clancy *et al.*, 1998; Stichtenoth and Frolich, 1998). Another potentially important mechanism by which iNOS-derived NO may promote RA is via its ability

to modulate cyclooxygenase 2 (COX-2)-dependent production of prostaglandins (Clancy *et al.*, 1998; Jang and Murrell, 1998; Stichtenoth and Frolich, 1998). Other mechanisms include NO-dependent promotion of chemotaxis of certain leukocytes *in vitro* (Beauvais *et al.*, 1995; Kaplan *et al.*, 1989).

Nitric oxide or NO-derived metabolites may also promote leukocyte infiltration in an indirect manner by enhancing the production of proinflammatory mediators such as IL-8 or TNF (Lander *et al.*, 1996; Villarete and Remick, 1995). Lander and co-workers have demonstrated that NO or one of its auto-oxidation products activates lymphocytes to produce

TNF (Lander *et al.*, 1996). Furthermore, NO may rapidly interact with certain reactive oxygen species such as O₂⁻ to yield the potent oxidant ONOO⁻ (Grisham *et al.*, 1999). Because of the large influx of phagocytic leukocytes such as PMNs, monocytes, and macrophages, it is not unreasonable to suggest that iNOS-derived NO could promote chronic gut inflammation by reacting with leukocyte-derived O₂⁻ to form ONOO⁻, which in turn upregulates cytokine and/or ECAM expression and injures the tissue.

One observation that has proved particularly troublesome when trying to delineate the “anti-inflammatory” mechanisms observed with certain NOS inhibitors is the inability

(or relative lack of efficacy) of certain NOS inhibitors when administered therapeutically, that is, when administered to animals with established disease (Table II). Two important concepts may help in clarifying this apparent paradoxical observation. First, NO is a potent vasodilator that enhances blood flow to most tissues (Ignarro, 1989; Radomski and Moncada, 1993). By and large most NOS inhibitors, especially those that inhibit the endothelial NOS (eNOS), will promote vasoconstriction and thus may remarkably reduce blood flow to a variety of different tissues (Conner *et al.*, 1999). Although selective iNOS inhibitors would not be expected to promote vasoconstriction via inhibition of eNOS, they could still theoretically reduce the hyperemia mediated by elevated levels of iNOS-derived NO. Because the delivery of leukocytes and inflammatory mediators to the inflamed synovia is blood flow dependent, a reduction in blood flow to the pannus via inhibition of NO production would be expected to inhibit the development of joint inflammation when the NOS inhibitor is administered prophylactically but not therapeutically (Fig. 5).

$$\text{Delivery} = \text{Blood flow} \times [\text{blood concentration}]$$

Figure 5 Role of blood flow in inflammation. Inflammation produces vasoactive mediators such as prostaglandins and NO, both of which will enhance blood flow and the delivery of leukocytes, mediators, and cytokines to the affected tissue. NOS inhibitors may attenuate this NO-dependent hyperemia, thereby limiting the delivery of leukocytes, cytokines, and mediators to the inflamed tissue and attenuating inflammation.

In addition to its vasoactive properties, NO is also thought to be an important mediator of angiogenesis, that is, it has been shown to promote blood vessel growth (Montrucchio *et al.*, 1997; Papapetropoulos *et al.*, 1997). If this is true, then NOS inhibitors may inhibit the development of pannus and thus attenuate joint inflammation when administered prophylactically but not therapeutically. Indeed, Cheresch and co-workers have demonstrated, using selective inhibitors of angiogenesis, significant anti-inflammatory activity in an experimental model of arthritis in rabbits (Storgard *et al.*, 1999). Furthermore, our data suggest that the selective proteasome inhibitor PS-341 may attenuate polyarthritis via a similar mechanism (Palombella *et al.*, 1998). Taken together, the literature demonstrates that NO possesses both anti-inflammatory as well as proinflammatory properties. The role that NO plays in the pathophysiology of chronic joint inflammation remains the subject of active debate.

Role of Nitric Oxide in Pain and Pain Perception

Chronic pain is one of the most serious symptoms associated with RA, and it can affect the quality of life of RA patients. Because chronic joint pain is difficult to treat, an understanding of the pathophysiological mechanisms that underlie pain is essential in order to design new therapeutic strategies to treat this debilitating disease.

Pain and Pain Pathways

Pain is defined by the International Association for the Study of Pain as “an unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage.” This broad definition includes pain that arises from acute injury as well as pain that occurs chronically as a result of ongoing pathophysiological processes. A key component of the definition is the emotional experience, because pain is always a perceived event and because individuals often respond differently to the same aversive stimulus, depending on their emotional state (Stimmel, 1997). The experience of pain is important to the survival of the individual because anticipation of pain produces aversion to a potentially harmful stimulus, and the pain experience prompts the individual to seek pain alleviation to enhance healing.

Tissue injury or pathophysiological processes such as inflammation activate peripheral nerve endings known as nociceptors that are responsive to noxious thermal, mechanical, or chemical stimuli. Thus, response to a stimulus that activates nociceptors is referred to as nociception in studies that utilize animal models, while humans can describe the actual experience of perceived pain. Untreated, persistent nociceptive pain continuously activates nociceptors and can lead to development of hyperalgesia and allodynia. Hyperalgesia is defined as enhanced pain to a noxious stimulus, whereas allodynia is described as pain produced by stimuli that are normally nonnoxious. Two types of hyperalgesia, primary

and secondary, have been described (Balter, 1992). Enhanced pain at the site of injury or inflammation is referred to as primary hyperalgesia. Secondary hyperalgesia occurs when enhanced pain is perceived after stimulation of sites away from the site of injury or inflammation.

Activation of peripheral nociceptors by noxious stimuli activates bipolar sensory afferent nerves with cell bodies in the dorsal root ganglia (DRG) (Fig. 6) and terminals in both the periphery and the central nervous system (CNS) (Bonica, 1990). The axons of these nerves are either nonmyelinated, slow (1 m/s) conducting C fibers or myelinated, fast (15 m/s) conducting A δ fibers. These nerves terminate in superficial layers of the dorsal spinal cord. Afferent input is integrated and modulated within the spinal cord through release of various mediators (see later). Nociceptive signals are then conducted to the brain through the spinothalamic tract to the thalamus and from the thalamus to areas of the cortex. The perception of pain likely occurs within the thalamus and surrounding areas (Fig. 6). Other spinal ascending systems, such as the spinoreticulohalamic tract, also contribute to overall pain transmission. Sensing of pain by the brain activates descending pain inhibitory control systems through corticospinal and reticulospinal tracts (Fig. 6). Signal integration occurs at several levels in the midbrain and medulla, in areas such as the periaqueductal gray (PAG) and the reticular formation. The hypothalamus and brain stem nuclei such as the locus coeruleus send input to the PAG, which provides descending input to the dorsal horn. These pathways terminate in the spinal cord to modulate the incoming nociceptive signals.

A number of substances are released in the periphery and in the spinal cord in response to nociceptive stimulation. Tissue injury and inflammation stimulate release of mediators such as histamine, prostaglandins (PGs), substance P (SP), bradykinin (BK), and leukotrienes that activate nociceptors. Stimulated nociceptors activate A δ and C fibers to stimulate the release in the spinal dorsal horn of peptides such as SP, neurokinin A, somatostatin, galanin, and calcitonin gene-related peptide (CGRP) as well as nonpeptide excitatory amino acids (EAAs, such as glutamate and aspartate), serotonin (5-HT), and PGs, among others (Coderre *et al.*, 1993; Wilcox, 1991). These mediators activate receptors in the dorsal horn to stimulate the ascending pain pathways to the brain. Perception of pain by the brain activates the descending pain inhibition pathways to release mediators in regions such as the PAG and in the spinal dorsal horn. These include opioid peptides, 5-HT, norepinephrine (NE), and adenosine as well as others. Release of these mediators alleviates pain, possibly by attenuating the spinal release of nociceptive mediators. Since the late 1980s, it has become evident that NO also has an important role in pain pathways.

The pain that follows actual nerve damage is referred to as neuropathic pain. This type of pain is characterized by causalgia (burning sensation), feelings of pin pricks, numbness, and tingling sensations (paresthesias) as well as hyperalgesia and allodynia. Neuropathic pain is reported after stroke (central pain), after limb amputation (phantom limb

pain), after deafferentation, during disease states such as diabetes and AIDS, and with other types of nerve injury. The mediators responsible for neuropathic pain are not well characterized. However, NE and 5-HT may be involved, since antidepressant drugs that inhibit reuptake of these neurotransmitters can alleviate some types of neuropathic pain. This type of pain is particularly difficult to treat because it is resistant to conventional agents such as nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids that are useful in nociceptive pain.

Development of hyperalgesia and allodynia following chronic pain is postulated to depend on sensitization of peripheral receptors as well as central sensitization (Coderre *et al.*, 1993). A key site of central sensitization is the spinal cord, considering that sensitization of spinal dorsal horn neurons is coincident with spreading areas of hyperalgesia (secondary hyperalgesia). Other CNS regions such as the thalamus and somatosensory cortex also show sensitized neuronal responses. The mechanism for central sensitization is not completely understood, but it is postulated to involve both neuropeptides and EAAs acting through second messenger systems and increases in intracellular calcium. Because increased intracellular calcium stimulates NOS to increase formation of NO, a role for NO may also be found in central sensitization. Increased expression of proto-oncogenes, particularly c-Fos, and transcriptional regulation of peptides such as dynorphin may also contribute to the hyperalgesic response.

Methods Used in the Study of Pain

Because pain is perceived, the most appropriate model for understanding mechanisms of pain transmission is the human. However, there are important caveats in human studies. One consideration is the individual variability of responses to the same noxious stimulus, as mentioned earlier. Owing to the underlying emotional component of pain, there is not a simple relationship between perceived pain intensity and noxious stimulus intensity. Also, many methods utilized for evaluating pain are not particularly objective. In spite of these factors, numerous devices such as visual analog scales, questionnaires, pictures of facial expressions, or other types of subjective pain grading methods have been used with reasonable success in clinical situations (Chapman and Syrjala, 1990; McGrath, 1989). Nonsubjective tests include electrodiagnostic evaluations of nerves and muscles (Stolov, 1990) and thermography (LeRoy and Filask, 1990). Investigations of experimentally induced pain in humans are also problematic. Studies measuring pain threshold (ability to discriminate when a stimulus becomes painful) and pain tolerance (unwillingness to receive more intense stimuli) in normal volunteers showed that although threshold and tolerance are related, they are different indices of pain perception (Harris and Rollman, 1983). The evaluation of experimentally induced pain should include measurements of both threshold and tolerance. Also, patients suffering pathophysiological pain have higher tolerance levels for experimentally induced

Figure 6 Major neuronal pathways that participate in pain transmission/modulation. In the ascending pain transmission pathway, painful stimuli activate peripheral nociceptors in skin, muscle, and viscera to activate A δ and C fibers that terminate in the dorsal horn of the spinal cord. Neurotransmitters are released here that activate the ascending spinothalamic tract, which terminates in the thalamus. Projections from the thalamus extend to specific areas in the cortex. Pain perception occurs in these brain areas. In the descending pain modulation pathway, pain perceived in brain structures activates neuronal pathways that synapse in various brain stem areas such as the periaqueductal gray (PAG) and reticular formation. Projections from the hypothalamus and other rostral structures also converge in the PAG to modulate signal transmission. Fibers descend to the spinal cord, where other neurotransmitters are released that modulate incoming painful stimuli. This is a very simplified diagram; there are many more pathways and brain stem nuclei involved in the integration of pain (Bonica, 1990).

pain than do patients without ongoing pain (Lipman *et al.*, 1987). Clearly, objective measurement of pain in humans is inherently difficult.

To facilitate the study of pain pathways, a number of animal models have been developed. Models for evaluation of nociceptive pain after noxious mechanical, thermal, or

chemical stimulation have been developed, and some of these are described in Table III. The time required (seconds) for the animal to respond is an indication of the nociceptive threshold of that animal. These tests are commonly used to evaluate antinociceptive effects of administered drugs that will increase the response latency times (hypoalgesia or

Table III Animal Models of Acute and Chronic Pain

Stimulus type	Species	Stimulus ^a	Response	Reference	
Acute					
Thermal	Heat	Mouse/rat	Radiant heat (tail)	Tail flick	D'Amour and Smith (1941)
		Rat	Radiant heat (paw)	Paw withdrawal	Hargreaves <i>et al.</i> (1988)
		Mouse/rat	Hot water (55°C)	Tail flick	Sewell and Spencer (1976)
			Hot plate	Jump or lick hind paw	Ankier (1974)
	Cold	Rat	Cold water (−10°C)	Tail flick	Pizziketti <i>et al.</i> (1985)
Mechanical		Rat	von Frey filaments	Paw withdrawal	Chaplan <i>et al.</i> (1994)
		Mouse/rat	Mechanical force	Paw withdrawal	Randall and Selitto (1957)
Chemical		Mouse/rat	Acetic acid, NaCl, BK, phenylquinone (i.p.)	Writhing	Vyklicky (1979)
			SP, EAAs (i.t.)	Licking, scratching	Wilcox (1988)
Chronic					
Inflammatory	Acute	Mouse/rat	Formalin (i.pl.)	Licking, shaking	Murray <i>et al.</i> (1988), Wheeler-Aceto and Cowan (1991)
			Carrageenan (i.pl.)	Thermal hyperalgesia	Garry <i>et al.</i> (1994a)
			CFA (i.pl)	Hyperalgesia	Millan <i>et al.</i> (1998)
			Yeast suspension (i.pl.)	Decreased mobility	Langford <i>et al.</i> (1972)
	Chronic	Rat	CFA (tail base)	Vocalization, hyperalgesia	Colpaert (1987); Calvino <i>et al.</i> (1987)
			PG/PS (i.p.)	Hyperalgesia	Fuseler <i>et al.</i> (1998)
Neuropathic					
		Rat	CCI	Hyperalgesia/allodynia	Bennett and Xie (1988)
			Partial sciatic nerve ligation	Hyperalgesia/allodynia	Seltzer <i>et al.</i> (1990)
			L5/L6 nerve ligation	Hyperalgesia/allodynia	Kim and Chung (1992)
			Spinal cord irradiation	Mechanical allodynia	Xu <i>et al.</i> (1992)

^ai.pl., intraplantar; i.p., intraperitoneal; i.t., intrathecal; CFA, Freund's complete adjuvant; BK, bradykinin; SP, substance P; EAA, excitatory amino acids; PG/PS, peptidoglycan polysaccharide; CCI, chronic constriction injury, sciatic nerve.

analgesia). A decrease in response latency time (hyperalgesia and allodynia) is observed in animal models of inflammation.

A number of models of acute inflammatory pain in which behaviors are quantified have also been described (Table III). One of the most widely used is the formalin test. In this test, formalin injected into a rat or mouse paw (intraplantar, i.pl.) elicits a two-phase behavioral response. In the first 5 min after formalin injection, there is flinching/shaking of the paw, and the animal licks the paw. These responses decline by 10 min and are followed by a secondary phase of the same responses beginning at about 15 min, peaking at around 20 to 30 min, and ending at about 60 min (Wheeler-Aceto and Cowan, 1991; Murray *et al.*, 1988). The early phase is thought to be due to direct activation of nociceptors, whereas the secondary phase likely represents an inflammatory response (Hunskar and Hole, 1987). In other models, inflammatory responses consist of a single acute behavioral phase that subsides within hours or days.

Evaluation of chronic inflammatory pain has been performed in animal models of arthritis (Table III). Administration of a heat-killed *Mycobacterium butyricum* (Freund's adjuvant) suspension intradermally into a rat tail base produces paw inflammation in about 7 days that peaks at around

day 18–20 and gradually subsides (Colpaert, 1987). Increased vocalization, decreased mobility (Colpaert, 1987), as well as mechanical hyperalgesia (Calvino *et al.*, 1987) occur with a similar time course, suggesting development of chronic pain associated with the inflammation. Preliminary studies measuring pain thresholds have been performed in the PG/PS model of polyarthritis described earlier (Wilder *et al.*, 1983). Results obtained thus far suggest that both mechanical allodynia and thermal hyperalgesia develop along with the increases in paw volume and arthritis index (Fuseler *et al.*, 1998).

Several animal models have been developed as mimics of neuropathic pain. Those listed in Table III include injury both to peripheral nerves and to the CNS. Mechanical and thermal allodynia and hyperalgesia as well as affected paw guarding and licking behaviors are observed in these models. These preparations are believed to represent models of human causalgia, dysesthesia (spontaneous pain), and paresthesias.

Nitric Oxide as a Pain Mediator/Modulator

Among the chemical mediators of pain, a role for NO in both nociceptive and neuropathic pain is gradually being

revealed. Studies in human volunteers show that when solutions containing NO are injected or infused intravenously (i.v.) into the hand, pain is produced, with the intensity dependent on the NO concentration (Holthausen and Arndt, 1995). The vasodilating activity of NO is at least partially responsible for development of pain. In many painful disorders characterized by inflammation, such as rheumatoid arthritis, enhanced NO production occurs, and there is a strong correlation between pain and skin hyperthermia (due to enhanced local vasodilation) (Anbar and Gratt, 1997). Release of NO is also hypothesized to be a trigger for spontaneous migraine pain (Thomsen and Olesen, 1998). The NO donor compound glycerol trinitrate (GTN, nitroglycerin) reliably produces headache in normal volunteers as well as patients who suffer from migraine (Iversen *et al.*, 1989). Although the mechanisms underlying NO involvement in migraine are unknown, dilation of cerebral arteries and direct activation of sensory nerve fibers have been suggested (Thomsen and Olesen, 1998). Nitric oxide thus appears to be a chemical link between peripheral and vascular nociception (Anbar and Gratt, 1998).

A CNS role for NO in pain is shown in animal studies. Injection of NO donor compounds such as sodium nitroprusside (SNP), hydroxylamine, and NOC-18 into the spinal cord produce a dose-dependent hyperalgesic response in the tail flick test that is blocked by hemoglobin (Hb), an NO scavenger (Inoue *et al.*, 1997; Kitto *et al.*, 1992). Similar effects are found for intracerebroventricular (i.c.v.) NOC-18 administration, but at doses that are almost 15-fold greater (Shibuta *et al.*, 1995), indicating a predominant role for spinal NO in tail flick hyperalgesia. When administered spinally, low (picomolar) doses of L-arginine, the endogenous NO precursor, facilitate tail flick nociception in accord with the proposed role of NO in mediating pain (Meller *et al.*, 1992). More direct evidence is derived from studies showing an increase in NO metabolites in spinal microdialysates after i.pl. injection of capsaicin, the component of hot peppers that produces secondary hyperalgesia and allodynia (Wu *et al.*, 1998a). This increase is blocked by pretreatment with a NOS inhibitor, suggesting that formation of spinal NO is increased in peripheral pain.

Chronic neuropathic pain induces changes in NOS expression and activity in the CNS. Increased expression of NOS protein (measured by immunoreactivity) is found in L5 and L6 DRG 2 weeks after L5/L6 spinal nerve ligation (Steel *et al.*, 1994). Activity of NOS also increases at this time point, but after 4 weeks it returns to prelesion values even though mechanical allodynia is still present (Choi *et al.*, 1996). A bilateral decrease in NOS activity is found in lumbar spinal cord tissue in the same animals at both the 2- and 4-week time points (Choi *et al.*, 1996). Others have found increased expression of NOS in neurons in the lumbar DRG and in ipsilateral dorsal roots, fibers, and terminals in the dorsal horn after sciatic nerve lesion (Zhang *et al.*, 1993). In these same animals, the numbers of NOS-immunopositive neurons in dorsal horn lamina were decreased. Thus, NOS in sensory neurons is upregulated, whereas NOS in dorsal

horn appears to decline. Studies using antisera selective for NOS isoforms have also shown changes in immunoreactivity in neuropathic pain models (see later). These alterations in NOS activity suggest that NO has an important role in neuropathic pain processing, but the exact relationships between pain and NO synthesis in discrete CNS regions are not clear.

Effects of Nitric Oxide Synthase Inhibitors on Pain

Inhibitors of NOS activity provide experimental evidence for the role of NO in pain. The pain evoked by injection of hyperosmolar solutions into human hand veins is completely blocked by pretreatment with the NOS inhibitor *N*^G-monomethyl-L-arginine (L-NMMA) (Kindgen-Milles and Arndt, 1996). Injection of BK into hand veins induces pain that is blocked by the NOS inhibitor *N*^G-nitro-L-arginine methyl ester (L-NAME), suggesting that BK-induced effects are mediated by release of NO (Holthausen, 1997). Clinical studies show that L-NMMA (546C88) is effective in acute treatment of migraine and chronic tension-type headache, although systemic side effects such as increased blood pressure may limit its therapeutic potential (Ashina *et al.*, 1999; Lassen *et al.*, 1997). Development of selective nNOS inhibitors may provide effective therapy for headache pain.

In animal models of neuropathic pain, inhibition of NOS activity alleviates pain behaviors. When administered systemically and continuously for 12 days in the chronic constriction injury (CCI) model, L-NAME is ineffective in reversing thermal (heat) hyperalgesia. However, when applied directly and continuously to the site of CCI, L-NAME prevents the development and maintenance of hyperalgesia (Thomas *et al.*, 1996). Systemically administered L-NAME reverses mechanical allodynia in other neuropathic pain models, an effect that is reversed by L-arginine (Hao *et al.*, 1994; Yoon *et al.*, 1998). Systemic L-NAME also reverses cold allodynia and cold-stress-exacerbated ongoing pain. As mentioned earlier, the EAAs released in the spinal cord after nerve injury activate *N*-methyl-D-aspartate (NMDA) receptors to increase intracellular calcium and activate NOS. Indeed, spinal administration of L-NAME as well as both NMDA and non-NMDA antagonists reduces nerve lesion-induced behaviors thought to be indicative of pain (Wong *et al.*, 1998). Also, in an animal model of painful radiculopathy from lumbar disk herniation, spinally administered L-NMMA reduces mechanical hyperalgesia (Kawakami *et al.*, 1998). Electrophysiological recordings from dorsal root ganglia show that L-NAME suppresses neuronal activity following sciatic nerve ligation, but not in nonligated conditions (Wiesenfeld-Hallin *et al.*, 1993). These and other studies indicate that NO plays an important role in pain produced by nerve injury.

Studies with NOS inhibitors have also suggested a role for NO in inflammatory pain. Both local and systemic administration of NOS inhibitors are effective in alleviating nociception. The thermal hyperalgesia found in the rat arthritis model of intraarticular (i.a.) kaolin/carrageenan is reversed by i.a. L-NAME (Lawand *et al.*, 1997). Mechanical

hyperalgesia induced by i.pl. PGE_2 is reversed by i.pl. L-NMMA, suggesting that the effects of peripheral PGE_2 are mediated through NO (Aley *et al.*, 1998). Similarly, i.pl. coinjection of L-NAME with formalin attenuates the second phase of the behavioral response in the formalin test (Kawabata *et al.*, 1994). Systemic L-NAME attenuates both mechanical and thermal hyperalgesia induced by i.pl. carrageenan (Handy and Moore, 1998) and inhibits the second phase of the formalin test as well (Morgan *et al.*, 1992). NOS activity in the CNS may be involved in some of the actions of systemic L-NAME, as spinally administered L-NAME attenuates the maintenance of thermal but not mechanical hyperalgesia in this model (Meller *et al.*, 1994). These effects of NOS inhibitors may be partially due to effects other than NOS inhibition, because L-NAME also inhibits production of PGs and interleukin (IL- 1β) (deMello *et al.*, 1997).

Electrophysiological studies in the spinal cord show that systemic L-NAME reduces the second but not the first peak of the neuronal firing response observed following i.pl. formalin (Haley *et al.*, 1992). Noxious mechanical stimulation of inflamed rat paws (from i.pl. carrageenan or mustard oil) produces an increase in spinal single motor unit reflex activity that is blocked by i.v. L-NAME (Semos and Headley, 1994). In noninflamed paws in these studies, L-NAME has no effect on the activity produced by mechanical stimulation, whereas it blocks noxious thermal nociceptive reflexes equally in inflamed and noninflamed paws. In addition, L-NAME has no effect on mechanical nociception in spinalized rats with inflamed paws. These results suggest a role for central NO in peripheral inflammation-induced mechanical, but not thermal, nociception. However, because the behavioral results implicate spinal NO in thermal but not mechanical hyperalgesia, the exact relationship between electrophysiological results and behavioral observations remains to be clarified.

Although most studies using NOS inhibitors to examine pain mechanisms have utilized models of neuropathic or inflammatory pain, these agents have also been tested in acute nociceptive pain models. When administered systemically, i.c.v., or spinally, L-NAME produces antinociception in the tail flick, hot plate, and acetic acid writhing tests (Moore *et al.*, 1991; Shibuta *et al.*, 1995; Yamaguchi *et al.*, 1996). Although the effect produced by i.c.v. L-NAME in the tail flick test is slight (15% analgesia), it is reversed by NOC-18 (Shibuta *et al.*, 1995). When compared to morphine, spinal L-NAME is 20- to 60-fold less potent, and i.v. L-NAME is about 30-fold less potent in this test (Yamaguchi and Naito, 1996). However, others have reported that spinally administered L-NAME does not produce tail flick antinociception in a dose that was effective in previous studies (Machelska *et al.*, 1997a,b). These differences in results point to other possible interpretations for NO actions in pain pathways.

Inhibitors of NOS activity also show that NO may not be a mediator for all types of pain. For example, in humans, i.v. L-NAME does not affect pain evoked by heat, cold, or stretch (Holthausen and Ding, 1997). The site of NO release is important; peripherally administered NOS inhibitors gen-

erally inhibit pain from peripheral stimuli. However, the role of centrally released NO may vary, depending on the type of pain stimulus. For instance, the tactile allodynia observed in a rat diabetic model is not reversed by spinally administered L-NAME (Calcutt and Chaplan, 1997). Also, spinally administered L-NAME is ineffective in reversing pain behaviors in a rat model of postoperative pain, a plantar incision (Zahn and Brennan, 1998). Further studies are needed to clarify the role of CNS NO in pain.

There is evidence that NO is also antinociceptive. When administered i.c.v., the precursor of NO, L-arginine (a constituent of kyotorphin, L-tyrosyl-L-arginine), produces antinociception that is proposed to be mediated via kyotorphin-induced release of endogenous opioid peptides (Kawabata *et al.*, 1993) as well as via activation of the NO-cGMP pathway (Ji and Zhu, 1993). Antinociception produced by i.c.v. or systemic L-arginine is blocked by systemic opioid antagonists (Kawabata *et al.*, 1992, 1993), suggesting involvement of CNS opioids. In support of the latter hypothesis, iontophoresis of a stable analog of cGMP to the rostroventral medulla, the brain stem region involved in pain suppression, produces cellular excitation that is inhibited by NOS inhibition (Hantall, 1995). In behavioral studies, i.c.v. administration of cGMP analogs produces antinociception in the tail flick test (Vocci *et al.*, 1978). At peripheral sites, methylene blue (MB, a guanylyl cyclase inhibitor), but not naloxone (an opioid antagonist), blocks antinociception produced by L-arginine in the carrageenan model (Kawabata *et al.*, 1992). Thus, NO may be important in antinociception as well as nociception. Indeed, i.c.v. L-arginine has been postulated to play a dual role in nociceptive processing, being nociceptive under conditions where NOS activity is inhibited and where either kyotorphin or opioid receptors are blocked (Kawabata *et al.*, 1993).

Evidence for NO as an antinociceptive mediator is found in studies using muscarinic agonists and NOS inhibitors. Antinociception in the hot plate and tail flick tests produced by muscarinic agonists administered both spinally and supraspinally is attenuated by L- N^G -nitroarginine (L-NNA) a nonselective NOS inhibitor (Iwamoto *et al.*, 1994a,b). Muscarinic agonist antinociception is also blocked by MB, suggesting involvement of the cGMP system. Endogenous agonists at muscarinic receptors could potentially activate the L-arginine/NO/cGMP cascade at multiple sites in the CNS during nociceptive stimulation to suppress pain.

Studies show that L-NAME inhibits the increase in c-Fos expression induced by GTN in brain areas associated with pain pathways, such as the nucleus tractus solitarius, the spinal trigeminal nucleus caudalis (NTC), and the periaqueductal gray, among others (Tassorelli *et al.*, 1997). Interestingly, L-NAME, which inhibits both neuronal and vascular endothelial NOS activity, is effective in most brain areas, whereas 7-nitroindazole (7-NI), a more specific inhibitor for neuronal NOS (nNOS), is effective in only in specific areas, such as the NTC. L-NAME also completely prevents the increase in c-Fos immunoreactivity found in spinal dorsal horn after i.pl. formalin injection (Roche *et al.*, 1996) and

after noxious mechanical stimulation (Lee *et al.*, 1992). The decrease in c-Fos production is associated with decreased behaviors in the formalin test, a measure of antinociception (Roche *et al.*, 1996). The relationship between c-Fos induction, NO, and pain is not well understood, but NO induction of c-Fos may be involved in activation of pain pathways.

Which NOS Is Involved?

Isoform-selective inhibitors of NOS suggest roles for both nNOS and iNOS in pain arising from inflammation. It is well established that iNOS production is associated with inflammatory situations that are accompanied by pain (Anbar and Gratt, 1997). A role for nNOS is also postulated. The nNOS-selective inhibitors 7-NI and 1-(2-trifluoromethylphenyl)imidazole (TRIM) inhibit carrageenan-induced thermal and mechanical hyperalgesia (Handy and Moore, 1998). Late phase formalin-induced behaviors are also reversed by 7-NI (Moore *et al.*, 1993). Involvement of eNOS in this action was discounted because 7-NI has no effects on vascular responses. However, these decreased pain behaviors may also result from the activity of 7-NI as an anti-inflammatory agent, because it also inhibits synthesis of PGs and cellular infiltration as well as nNOS activity (Salvemini *et al.*, 1995). In accordance with the decreased pain behaviors, 7-NI but not aminoguanidine, an iNOS inhibitor, reduces joint inflammation when administered following development of polyarthritis after injection of Freund's complete adjuvant (Pozza *et al.*, 1998). Although pretreatment with aminoguanidine or *N*-iminoethyl-L-lysine (L-NIL, a selective iNOS inhibitor) prevents development of adjuvant-induced arthritis (Connor *et al.*, 1995), when given after the polyarthritis has developed, L-NIL has no effect on joint inflammation (Fletcher *et al.*, 1998). These findings suggest that nNOS but not iNOS is involved in maintenance of established inflammation and pain.

Studies using transgenic mice deficient in nNOS further refine the role for NO in pain. In nNOS-deficient mice, the nociceptive responses to formalin are not different from those in wild-type mice (Crosby *et al.*, 1995). Interestingly, although L-NAME completely prevents the second phase of the formalin test in wild-type mice, the NOS inhibitor does not have this effect in the nNOS-deficient mice. These results suggest that NO is sufficient but not essential for expression of nociception.

The role of NOS isoforms in neuropathic pain has also been studied using selective inhibitors. The mechanical allodynia in spinal cord lesioned rats is reversed by systemically administered 7-NI (Hao and Xu, 1996). The effects of 7-NI are reversed by L-arginine, and the NOS inhibitor has no effects on blood pressure at the doses used, suggesting that the antiallodynic effects are not mediated through eNOS. In the CCI model, both L-NAME and aminoguanidine reverse the increase in local blood flow that occurs at the nerve constriction (Levy and Zochodne, 1998). Others, using 7-NI in electrophysiological studies after spinal nerve L5 lesions, have suggested that nNOS is not involved in the

generation of spontaneous activity of lesioned afferents, but other NOS isoforms are probably activated (Habler *et al.*, 1998). The investigators postulated that nNOS activity may be more important as a facilitator of nociceptive transmission than in the generation of spontaneous activity.

Expression of NOS immunoreactivity in neuronal tissues has been measured in attempts to determine roles of various isoforms in pain. In rat neuropathic pain models (CCI or tight ligature), nNOS immunoreactivity decreases in the spinal dorsal horn ipsilateral to the injury and increases in the DRG (Goff *et al.*, 1998). Activity of peripheral NOS may also increase, as both eNOS and nNOS immunoreactivity increases in the endoneurium of the ligated nerve in this model. Similar results were reported in a model of polyarthritis (Pozza *et al.*, 1998). The appearance of iNOS immunoreactivity at the nerve constriction site in the same model parallels the appearance of macrophages following nerve injury (Levy and Zochodne, 1998). The role of spinal nNOS in peripheral inflammation is not clear, as some investigators report no change in nNOS after inflammation induced by i.pl. Freund's adjuvant (Goff *et al.*, 1998) or carrageenan (Traub *et al.*, 1994), but others show an increase in dorsal horn nNOS-immunopositive neurons (Lam *et al.*, 1996). No iNOS immunoreactivity was detected in the dorsal horn after either neuropathic or inflammatory pain induction (Goff *et al.*, 1998). Other studies using an arthritis model of i.a. Freund's adjuvant show an increase in nNOS immunoreactivity in the lumbar (but not cervical) spinal dorsal horn and an increase in iNOS staining in ependymal cells around the central canal of the lumbar spinal cord (Wu *et al.*, 1998b). A recent review summarizes these and other findings and concludes that weak nociceptive input induces mainly an increase in nNOS that may be followed by a decrease after several days, whereas a strong nociceptive input causes mainly a persistent decrease in nNOS (Callsen-Cencic *et al.*, 1999).

Mechanisms of NO in Producing or Alleviating Pain

The exact mechanisms by which NO produces pain are not well understood. Because NO activates soluble guanylyl cyclase and increases cGMP concentrations, involvement of the NO-cGMP pathway in nociception has been suggested. Indeed, MB, a guanylyl cyclase inhibitor, blocks i.v. BK-induced pain in humans (Holthausen and Ding, 1997). Animal studies support this hypothesis. For example, the tail flick hyperalgesia produced by i.c.v. NOC-18 (Shibuta *et al.*, 1995) and the i.c.v. NOC-18-induced enhancement of nociception in the second phase of formalin-induced inflammation are completely abolished by MB (Shibuta *et al.*, 1996). Intradermal injections of the NO donor compound 3-(4-morpholinyl)sydnominine (SIN-1) into rat paws produces a mechanical hyperalgesia that is blocked by the guanylyl cyclase inhibitor 1*H*-[1,2,4]oxadiazolo[4,3-*a*]quinoxalin-1-one (ODQ) (Aley *et al.*, 1998). Immunohistochemical studies show high levels of cGMP-dependent kinase I (cGKI) expression in a subpopulation of rat DRG

neurons that partially overlap with SP- and CGRP-containing neurons (Qian *et al.*, 1996). Neuronal NOS is coexpressed with cGKI in these sensory neurons during embryonic development. The NO donor agent SNP causes an increase in release of immunoreactive SP, CGRP, and cGMP from spinal dorsal horn slices. The release of both cGMP and CGRP is inhibited by MB, suggesting an association between CGRP release and activation of guanylyl cyclase (Garry *et al.*, 1994b).

There is also evidence that additional mechanisms not involving cGMP may be involved in NO-induced pain, possibly depending on the site of NO release. For instance, MB does not affect the hyperalgesia induced by spinally administered NOC-18, indicating that cGMP is not involved in spinal NO-mediated nociception (Inoue *et al.*, 1997). Similarly, in the CCI model of neuropathic pain, spinally administered NOC-18 shortens the time to paw thermal hyperalgesia, an effect blocked by Hb, but not by MB (Inoue *et al.*, 1998). Also, the mechanical hyperalgesia produced by i.pl. PGE₂ is not reversed by coinjection with ODQ, but it is blocked by NOS inhibition (Aley *et al.*, 1998).

The pain produced by NO may be due to effects on ion channel activity (reviewed in Fagni and Bockaert, 1996). These effects may be through direct actions on glutamate-gated channels or through indirect actions mediated by cGMP. Nitric oxide-induced nociception may depend on formation of free radical species such as peroxynitrite, because a free radical scavenger, 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPOL), blocks thermal hyperalgesia in the CCI model (Tal, 1996). However, although inflammation occurs following injection of peroxynitrite directly into a rat paw, mechanical hyperalgesia is not observed (Ridger *et al.*, 1997).

Nitric oxide may also produce nociception indirectly through release of other nociceptive mediators. The SNP-induced release of immunoreactive SP and CGRP from rat spinal dorsal horn is attenuated by Hb, indicating dependence on NO. However, release of these peptides is also stimulated by sodium ferricyanide, which does not generate NO, suggesting that both NO-dependent and NO-independent mechanisms are involved in release (Garry *et al.*, 1994b). Superfusion of SNP onto parietal cortex of cats results in arterial vasodilation that is blocked by a CGRP antagonist and by LY83583, an inhibitor of guanylyl cyclase activity (Wei *et al.*, 1992). Interestingly, although LY83583 completely blocks vasodilation induced by applied CGRP, the SNP-induced vasodilation is only partially attenuated, suggesting an effect of SNP that is not mediated by cGMP. In the periphery, NO donor compounds also induce release of CGRP, possibly through formation of PGs (Holzer *et al.*, 1995).

Although nociceptive stimuli induce the release of BK and SP, pain produced by these peptides is likely mediated through NO because BK- or SP-induced pain is blocked after inhibition of NOS (Kindgen-Milles and Arndt, 1996). Inhibitors of NOS also block peripheral SP-induced vasodilation and plasma extravasation, symptoms associated with pain

(Ralevic *et al.*, 1995). The expression of NOS in neurons in the lumbar dorsal root ganglia and in the spinal cord dorsal horn is increased after sciatic nerve lesion, suggesting enhanced activity in neuropathic pain. Some of these same DRG neurons also express CGRP and SP (Zhang *et al.*, 1993).

It must be remembered that some types of pain are alleviated by increasing the levels of NO. The vasodilator activity of oral nitrates, by increasing NO levels, is well known to alleviate anginal pain (Thadani, 1997). In addition, transdermal GTN has been shown to be effective in treatment of pain associated with primary dysmenorrhea (Anonymous, 1997). However, headache (which may be the result of cerebral vasodilation; see earlier) was reported as a side effect in about 20% of patients studied. In patients with interstitial cystitis, pain is relieved and urinary NOS products are increased after treatment with oral L-arginine, a NO precursor (Smith *et al.*, 1997; Wheeler *et al.*, 1997). Lower pain scores in patients with acute vaso-occlusive sickle-cell crisis are associated with elevated blood levels of NO metabolites, suggesting that lowering NO may enhance the pain in this disease (Lopez *et al.*, 1996). Animal studies utilizing the formalin test show that L-arginine, the precursor for NO, is hyperalgesic or analgesic, depending on the dose, when injected into a paw. Low doses are hyperalgesic, an effect reversed by L-NAME, whereas a 10-fold higher dose is analgesic (Kawabata *et al.*, 1994).

Role of NO in Activity of Analgesic Drugs

OPIOIDS

In the postulated role of NO as a mediator of antinociception, it has been suggested that NO mediates the analgesia produced by morphine and other opioids. Interplantar morphine in rats reverses the hyperalgesia produced by interplantar PGE₂, an action that is blocked by pretreatment with MB and NOS inhibition (Ferreira *et al.*, 1991). These results suggest a role for the NO–cGMP pathway in peripheral morphine antinociception. In acute thermal pain tests, i.c.v. and spinally administered NOS inhibitors attenuate and L-arginine enhances morphine-induced antinociception, suggesting a central as well as a peripheral role for NO in morphine effects (Pataki and Telegdy, 1998; Song *et al.*, 1998; Xu and Tseng, 1995). In support of these behavioral studies, systemic morphine was shown to increase release of nitrite (a stable NO metabolite) in spinal cord microdialysates (Xu *et al.*, 1997). In contrast, others have shown that inhibition of spinal NOS enhances the antinociceptive effects of morphine and opioid receptor-selective agonists in both the acute thermal and pressure nociceptive tests as well as in inflammatory models (Machelska *et al.*, 1997a,b; Yamaguchi and Naito, 1996). These conflicting results suggest a role for NO in opioid effects, but the relationships are not clear.

Studies utilizing antisense oligodeoxynucleotides (ODN) to selectively downregulate isoforms of NOS have provided additional support for a role of NO in morphine effects and suggest possible explanations for previous conflicting results

using NOS inhibitors. Downregulation of a truncated form of nNOS at both the spinal and supraspinal levels blocks tail flick antinociception induced by systemic morphine (Kolesnikov *et al.*, 1997). Treatment with antisense ODN for the full-length nNOS does not affect acute morphine antinociception, but it blocks development of tolerance to the chronically administered opioid. Use of antisense ODN to iNOS has no effect on morphine antinociception. The antinociceptive effects of morphine are thus regulated in complex ways by the expression of various forms of NOS.

The role of NOS activity in development of tolerance to the antinociceptive effects of opioids is also complex. Several reports show that NOS inhibitors attenuate morphine-induced tolerance (Kolesnikov *et al.*, 1993; Pataki and Telegdy, 1998) and physical dependence (Adams *et al.*, 1993; Dambisya and Lee, 1996; Vaupel *et al.*, 1997). In these studies, morphine tolerance was induced by chronic treatment with subcutaneous morphine. However, continuous spinal infusion of L-NAME with morphine showed development of tolerance and physical dependence to morphine that was not substantially different from that which developed after infusion of morphine alone (Dunbar and Yaksh, 1996). The differences between these results could be due to the different routes of morphine administration, namely, peripheral versus central. When total cellular NOS mRNA or tissue homogenate NOS activity was measured, no change in brain or spinal cord mRNA or NOS activity in brain stem and cerebellum is found after chronic systemic morphine treatment (Babey *et al.*, 1994). However, repeated treatment with peripheral morphine increases NOS mRNA and NOS immunoreactivity in spinal cord slices measured by *in situ* hybridization and immunohistochemical methods (Machelska *et al.*, 1997a,b). Thus, adaptive changes of NOS probably occur in selective neurons throughout the CNS during development of morphine tolerance.

Pretreatment with a nonanalgesic dose of L-arginine has been shown to enhance (Pataki and Telegdy, 1998) and to have no effect on (Xu and Tseng, 1993) morphine-induced antinociception. Repeated treatment with i.c.v. or peripheral L-arginine is reported to enhance development of tolerance to systemic morphine (Pataki and Telegdy, 1998; Babey *et al.*, 1994). The mechanism for this effect may be attributed to findings that chronic treatment with systemic L-arginine decreases levels of morphine in specific brain regions and spinal cord (Bhargava *et al.*, 1997). The decreased morphine levels in the CNS result in a decreased antinociceptive potency of morphine that may appear to be an enhancement of tolerance.

Studies show that the NO-releasing drug FK409, injected locally, enhances the antinociceptive actions of systemically administered opioids in the formalin test (Nozaki-Taguchi *et al.*, 1998a,b). These results are difficult to reconcile with studies showing that systemic L-NAME plus morphine produce synergistic antinociception in the tail flick test (Yamaguchi and Naito, 1996). Thus, both increased NO and decreased NOS activity enhance morphine antinociception. This apparent discrepancy could be due to the different types

of pain measured, namely, inflammatory versus acute thermal nociceptive. Resolution of these differences awaits further studies.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

It has been proposed that one mechanism by which some nonsteroidal anti-inflammatory drugs (NSAIDs) alleviate pain and inflammation is by inhibition of expression of iNOS and decreased production of NO as shown in lipopolysaccharide (LPS)-stimulated macrophages (Aeberhard *et al.*, 1995; Amin *et al.*, 1995). This effect may or may not be due to direct inhibition of iNOS catalytic activity, but NSAID-induced decreased levels of iNOS mRNA and decreased protein expression are a common finding. Interestingly, antinociceptive synergism between peripheral L-NAME and NSAIDs in the formalin test and in the acetic acid writhing test has been reported (Morgan *et al.*, 1992). These effects may be mediated through decreased production of NO, decreased release of PGs, or both.

Effects of NSAIDs in the CNS may also be mediated through NOS inhibition. Ibuprofen inhibits iNOS mRNA and protein expression in glial cell cultures, where it has no effect on cyclooxygenase mRNA expression (Stratman *et al.*, 1997). The greater potency for ibuprofen to inhibit protein expression and iNOS activity than to inhibit mRNA production suggests that NSAIDs may inhibit posttranslational processing. However, the NSAID dipyrrone has no significant effect on brain nNOS activity (Bierith *et al.*, 1998), and a role for inhibition of nNOS activity in NSAID actions has not been reported.

In fact, the NO-cGMP pathway has been proposed to mediate the analgesic effects of NSAIDs. Local administration of NOS inhibitor or MB abolishes diclofenac-induced analgesia in the animal models of acute inflammatory pain (Tonussi and Ferreira, 1994). Others showed that dipyrrone administered i.c.v. has no effect on intraplantar PG-induced hyperalgesia, but systemic, intraplantar, and spinally administered dipyrrone reverse the hyperalgesia. Both L-NMMA and MB abolish the antinociceptive effects of dipyrrone administered by all these routes, suggesting involvement of the NO-cGMP pathway in dipyrrone effects. Thus, spinal and peripheral, but not brain, NO may mediate the analgesia produced by this NSAID (Lorenzetti and Ferreira, 1996).

Following these and other studies, a class of NO-releasing NSAIDs are being developed that produce less gastrointestinal injury than the NSAIDs. For example, NO-naproxan shows greater analgesic activity than naproxan in the acetic acid writhing test (Davies *et al.*, 1997). Although these drugs may represent improved therapy for pain, further studies are needed to clarify the role of NO in NSAID analgesia.

OTHER DRUGS

As mentioned earlier, neuropathic pain is often resistant to treatment by standard analgesic agents, namely, NSAIDs and opioids, but it can be alleviated by administration of antidepressants. Amitriptyline, imipramine, or other tricyclic antidepressants are effective in neuropathic pains. More

recently, imipramine, desipramine, and nortriptyline were shown to attenuate the nociceptive jaw opening reflex, and L-NAME blocked this activity (Ahn *et al.*, 1998). The role of NO in the analgesic action of antidepressants remains to be defined.

Inhibitors of NOS decrease the minimum alveolar concentration required for isoflurane anesthesia, suggesting augmentation of analgesic/anesthetic effects (Pajewski *et al.*, 1996). Of the two inhibitors tested, L-NAME produced a significant increase in blood pressure, whereas the nNOS-selective inhibitor 7-NI did not. Both drugs have similar effects on the isoflurane anesthesia. These studies suggest that nNOS, but not eNOS, is involved in the observed effect. Additional experiments will determine whether clinical advantage in anesthesia can be obtained with selective NOS inhibitors.

Capsaicin, the active component of hot peppers, is effective in relieving both neuropathic and inflammatory pain when applied to the site of pain origin. This analgesic effect is believed to be due to depletion of neuronal SP because capsaicin also produces pain by releasing SP. Animal studies show that antinociception produced by spinally administered capsaicin is prevented by inhibition of NOS activity and guanylyl cyclase activity (Kreeger *et al.*, 1994). Thus, the NO-cGMP pathway may also be involved in the analgesic activity of capsaicin.

Although the actions of many analgesics appear to involve NO in some way, not all drugs that produce analgesia have been shown to act by this mediator. For example, the antinociceptive effects of Δ^9 -tetrahydrocannabinol are not affected by NOS inhibitors (Thorat and Bhargava, 1994).

Conclusion

There is a great deal of evidence supporting a role for NO in pain and nociception as well as in analgesia and antinociception. However, the exact mechanisms by which NO affects pain pathways remain to be clarified. The use of NOS inhibitors or NO releasers as analgesic agents to treat specific pains without the undesirable side effects of other currently used drugs remains an intriguing possibility.

Acknowledgments

Some of the work reported in this chapter was supported by the Arthritis Center of Excellence at LSU Medical Center in Shreveport. We thank Ms. Laura Gray and Mr. Stephen Laroux for help in the preparation of the figures.

Nitric Oxide and Cancer

Georgette M. Buga and Louis J. Ignarro

*Department of Medical and Molecular Pharmacology
UCLA School of Medicine, Center for the Health Sciences
Los Angeles, California*

CARCINOGENESIS IS A MULTISTEP PROCESS. IT STARTS WITH ACCUMULATION OF MUTATIONS CAUSED BY ENVIRONMENTAL OR HEREDITARY FACTORS THAT LEAD TO MALIGNANT CELL TRANSFORMATION, LOCAL INVASION, AND METASTASIS TO DISTANT SITES. THE MAIN TARGETS OF MUTAGENESIS ARE GENES THAT PROMOTE OR INHIBIT CELL GROWTH AND GENES THAT CONTROL DNA REPAIR AND APOPTOSIS.

THE ROLE OF NITRIC OXIDE (NO) IN CARCINOGENESIS, TUMOR PROGRESSION, AND CANCER THERAPY IS MULTIFACETED AND DEPENDENT ON A VARIETY OF CONDITIONS THAT EXIST IN THE CELL MILIEU. NO HAS BEEN SHOWN TO HAVE BOTH TUMORICIDAL AND TUMORIGENIC EFFECTS, AND MODULATION OF NO LEVELS IN TUMOR MICROCIRCULATION CAN AFFECT TUMOR HEMODYNAMICS AND CANCER THERAPY. TUMOR SURVIVAL DEPENDS ON ADEQUATE BLOOD FLOW TO SUPPLY NUTRIENTS AND OXYGEN AND TO MAINTAIN A SUITABLE PH. NO PRODUCED BY THE TUMOR CELLS MAINTAINS THESE OPTIMAL CONDITIONS, BUT IT ALSO REDUCES THEIR ABILITY TO GROW AND METASTASIZE BY INHIBITING DNA SYNTHESIS AND MITOCHONDRIAL RESPIRATION. HIGH NO LEVELS ARE GENERALLY TUMORICIDAL, AND THIS IS A THERAPEUTICAL APPROACH THAT CAN BE USED FOR TUMOR CELLS THAT ARE SUSCEPTIBLE TO NO-MEDIATED APOPTOSIS. IT IS POSSIBLE THAT THE MAJORITY OF TUMOR CELLS CONTAINING HIGH NO LEVELS UNDERGO AUTOLYSIS, AND THE NO-RESISTANT ONES ARE THEN ABLE TO USE NO TO THEIR ADVANTAGE AND PROMOTE TUMOR PROGRESSION AND METASTASIS. THE ANTITUMOR ACTIVITY OF NO INCLUDES INHIBITION OF TUMOR CELL PROLIFERATION, PROMOTION, AND DIFFERENTIATION AND INCLUDES REDUCTION OF THE METASTATIC SPREAD IN CERTAIN TYPES OF CANCERS. THE ANTIMETASTATIC EFFECT OF NO OCCURS EITHER BY APOPTOSIS OR BY ALTERATIONS IN THE GENES THAT REGULATE METASTASIS. ANGIOGENESIS AND APOPTOSIS CAN ALSO BE REGULATED BY NO, WHICH HAS BEEN SHOWN TO BE BOTH AN INHIBITOR AND STIMULANT OF THESE PROCESSES.

THUS NO HAS THE UNIQUE ABILITY TO INITIATE AND/OR TO ARREST TUMOR FORMATION. ULTIMATELY, THE ROLE OF NO IN CANCER IS DETERMINED BY THE INTERACTION BETWEEN THE PROTECTIVE AND DESTRUCTIVE SIGNALING PATHWAYS IN A GIVEN CELL MILIEU.

Introduction

Nitric oxide (NO) is an essential molecule that mediates a number of cellular events. It has regulatory functions in the vascular and nervous systems, along with cytoprotective or cytotoxic actions that occur in inflammatory responses to infection, cancer, and transplant rejection. Nitric oxide is

clearly involved in the regulation of physiological homeostasis, and owing to its paradoxical abilities to protect and/or damage tissues, NO is involved in a number of pathophysiological states as well.

The role of NO in carcinogenesis, tumor progression, and cancer therapy is multifaceted and dependent on the cell microenvironment. NO may influence the fate of the host,

Table I Reactive Oxygen Species (ROS)

Name	Formula
Alkoxyl radical	RO·
Hydroxyl radical	·OH
Hydroperoxyl radical	HO ₂ ·
Hydrogen peroxide	H ₂ O ₂
Hydrobromous acid	HOBr
Hypochlorous acid	HOCl
Ozone	O ₃
Peroxyl radical	RO ₂ ·
Singlet oxygen	¹ O ₂
Superoxide	O ₂ ⁻

tion, nitrosamine generation, nitrotyrosine formation, etc.). The occurrence of this type of chemistry can result in oxidative, nitrosative, and nitrative stresses in cells.

Indirect Effects of Nitric Oxide

One of the most widely studied RNOS is the product of the reaction of NO with O₂⁻, peroxynitrite anion (ONOO⁻) (Fig. 1, Table II). This species is capable of inducing all three forms of cellular stresses mentioned earlier. Under acidic conditions ONOO⁻ is protonated (pK_a = 6.8) to form peroxynitrous acid, which decomposes rapidly to generate nitrate (NO₃⁻). It is thought that reactive species such as nitrogen dioxide (·NO₂), the highly reactive hydroxyl radical (HO·), and/or other highly oxidizing species can be gener-

ated on the decomposition pathway of ONOO⁻ to NO₃⁻. The generation of these reactive ONOO⁻ decomposition intermediates may be responsible for the oxidizing nature of ONOO⁻. In the presence of Lewis acids such as cupric ion, peroxynitrite can be cleaved heterolytically to generate hydroxide ion (OH⁻) and nitronium ion (NO₂⁺). This reaction has been proposed to be catalyzed by the antioxidant enzyme copper–zinc superoxide dismutase (Cu,Zn-SOD). If formed, NO₂⁺ is a potent oxidant capable of nitrating protein tyrosine residues to form 3-nitrotyrosine. Indeed, the detection of nitrotyrosine has been used as a marker for ONOO⁻ generation *in vivo* and *in vitro*. Peroxynitrite may also react with NO or O₂⁻ and form NO₂, which in turn, by reacting with NO, forms dinitrogen trioxide (N₂O₃), a strong nitrosating agent. Since ONOO⁻ reacts further with its biosynthetic precursors, an excess of either NO or O₂⁻ may limit the lifetime of peroxynitrite. Also a number of factors that may interfere *in vivo* with the reaction of O₂⁻ and NO, such as SOD, oxyhemoglobin (HbO₂), or diffusion, may further limit peroxynitrite formation. The cellular sites most likely to produce peroxynitrite are mitochondria, where O₂⁻ is produced during aerobic respiration. Peroxynitrite is nucleophilic and can react with biological electrophiles. One of the most abundant biological electrophiles is carbon dioxide (CO₂). In fact, this reaction likely represents the predominant reaction pathway for biological ONOO⁻. The adduct of ONOO⁻ with CO₂, nitrosoperoxycarbonate (ONOOCO₂⁻) is capable of decomposing to NO₃⁻ and nitrating tyrosine. Thus, reaction of ONOO⁻ with CO₂ may represent a mechanism for degrading/activating ONOO⁻ without the intermediacy of ONOOH.

Reaction of NO with O₂ generates ·NO₂, which is a reactive radical and potent oxidant capable of inducing cytotoxicity. Nitrogen dioxide reacts readily with NO to form N₂O₃. This species is a potent nitrosating agent (i.e., it adds the elements of NO⁺ to nucleophilic species) and may be biologically accessible under conditions of high NO production. Nitrosation of biological amines, to form nitrosamines, and nitrosation of thiols, to form S-nitrosothiols (RSNO), have been observed and may represent a crucial process in NO biology. Cellular consequences resulting from the reaction of NO with O₂⁻ and O₂⁻-derived species are myriad and include potential DNA damage and cell death (Fig. 2).

As mentioned earlier, nitrosamine formation can result from the oxidation of NO to N₂O₃ followed by reaction with amine. Dinitrogen trioxide can also be generated from acidic nitrite (NO₂⁻) and, in fact, is the preferred reagent for nitrosation in chemical synthesis. Nitrosamines are found in food, cigarette smoke, and can be generated via ingested nitrite, which forms N₂O₃ in the acidic conditions present in the stomach (Table XII). Activated immune cells also produce nitrosamines.

S-Nitrosothiols (RSNO) can be formed from the reaction of nitrosonium ion (NO⁺), with thiols. Although NO⁺ is, for the most part, biologically inaccessible, its chemical equivalents can be generated under physiological conditions. For example, N₂O₃ or select metal-bound nitrosyls are capable

Table II Reactive Nitrogen Oxide Species (RNOS)

Name	Formula
Alkyl peroxynitrites	ROONO
Dinitrogen trioxide	N ₂ O ₃
Dinitrogen tetroxide	N ₂ O ₄
Dinitrogen pentoxide	N ₂ O ₅
Nitric oxide	NO·
Nitrite	NO ₂ ⁻
Nitrous acid	HNO ₂
Nitrogen dioxide	NO ₂ ·
Nitronium cation	NO ₂ ⁺
Nitrosonium ion	NO ⁺
Nitroxyl	HNO
Nitroxyl anion	NO ⁻
Nitrate radical	NO ₃ ·
Nitrous oxide	N ₂ O
Peroxynitrite anion	ONOO ⁻
Peroxynitrite radical	ONOO·
Peroxynitrous acid	ONOOH

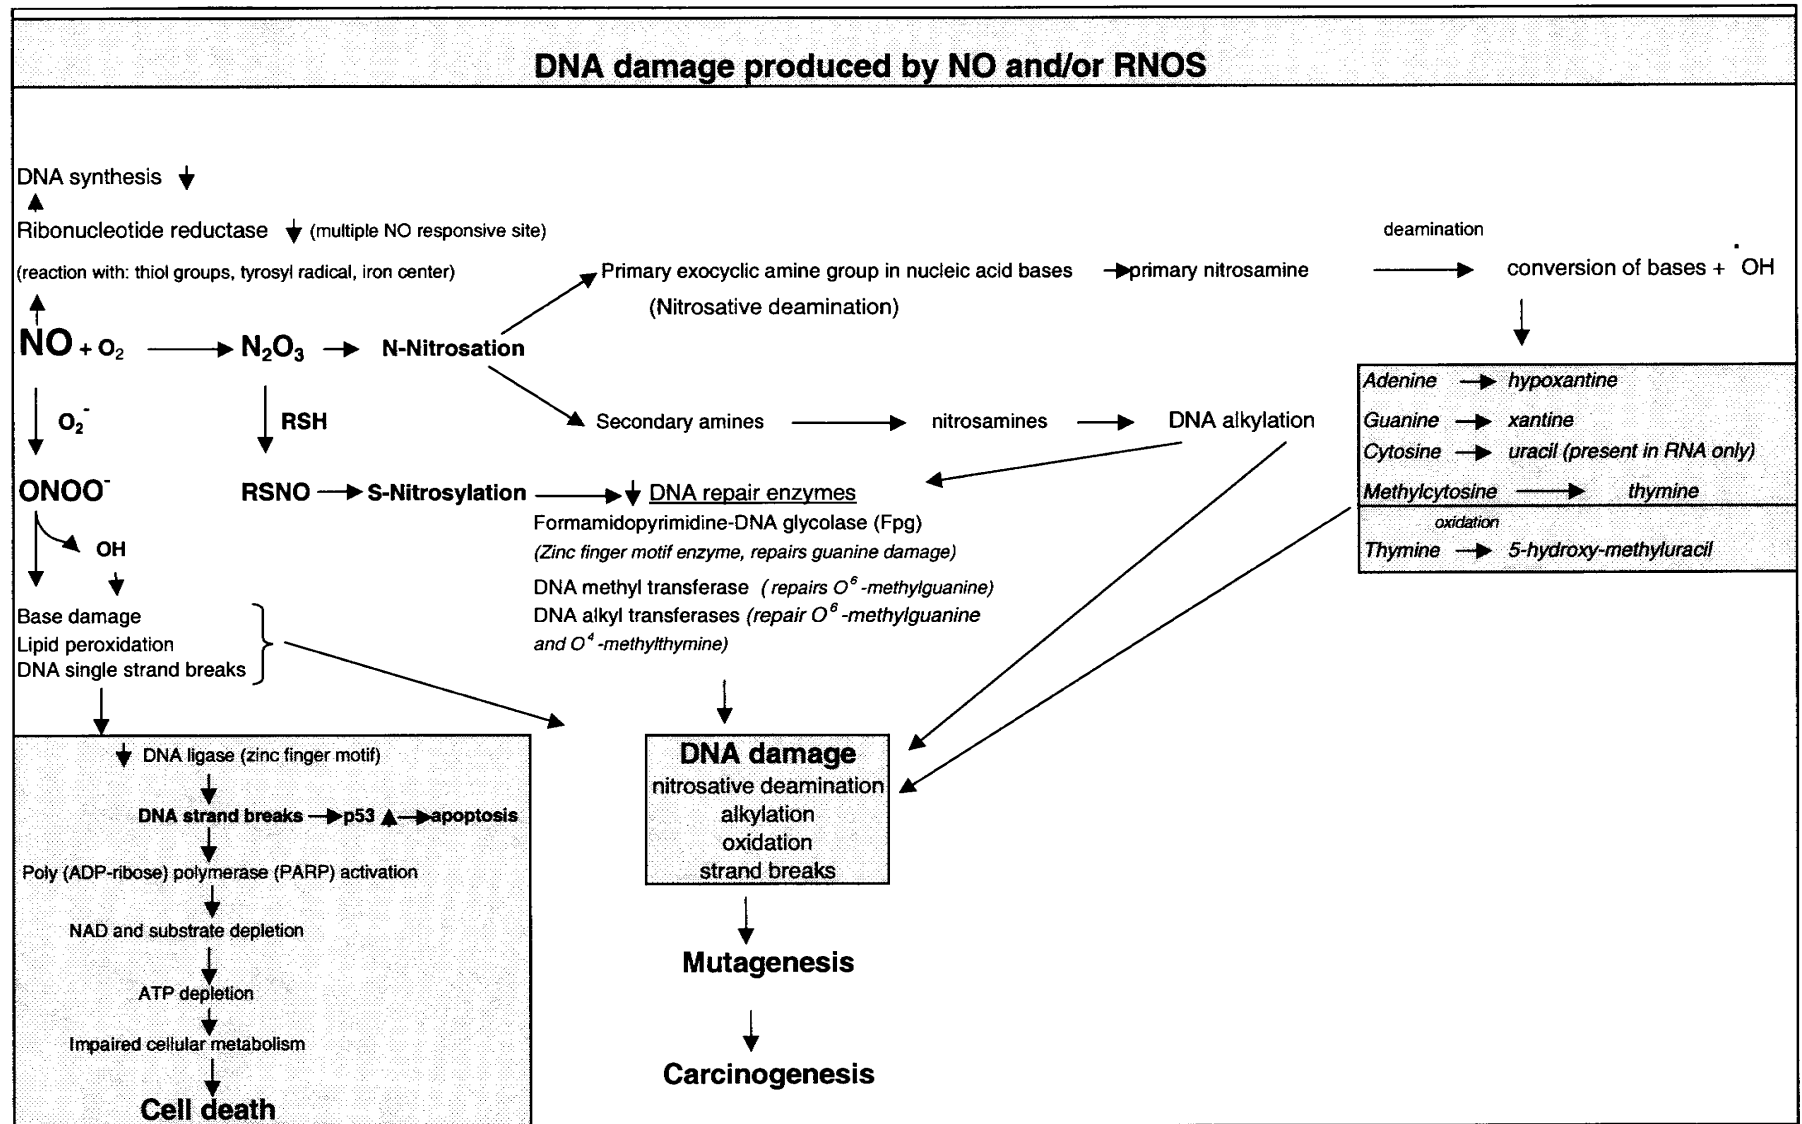

Figure 2 Effects of nitric oxide (NO) and RNOS on the nuclear DNA in mammalian cells.

of serving as a chemical equivalent to NO^+ and may participate in nitrosation chemistry. Nitrosation of thiols has multiple cellular effects ranging from modulation of signal transduction to carcinogenesis and cell death. S-Nitrosylation of enzymes can produce conformational changes that affect the enzyme–substrate interactions, and a number of enzymes that contain key sulfhydryl groups at their active sites are inhibited by S-nitrosylation (Table III).

The biochemical interrelationship of NO with RNOS and ROS is complex and, as expected, the cellular outcomes are highly dependent on the exact nature of these interactions. The reaction of NO with O_2^- , for example, may activate NO to produce a reactive and highly oxidizing species. Alternatively, the reaction of NO with O_2^- may decrease the biological activity of O_2^- , which may be cytotoxic on its own. Furthermore, reaction of NO with the highly toxic $\text{HO}\cdot$ would result in the generation of a much weaker oxidant, NO_2^- . Thus, it may be expected that NO can serve as either a cytoprotective or cytotoxic species, depending specifically on the cellular environment and the mechanism of toxicity. Indeed, it has been reported that NO can serve to protect cells from free radical damage as well as promote cellular demise.

CYTOTOXIC ROLE OF NITRIC OXIDE

The cytotoxicity of NO affects both cGMP-dependent and -independent mechanisms, and it contributes to the oxidative damage induced by ROS, alkylating agents, and free

heavy metals ions. NO has the ability to release heme from some heme-containing proteins, such as the cytochrome P-450 family of enzymes. The released heme triggers the activation of heme oxygenase, which in turn hydrolyzes cellular heme complexes, and cytotoxic free iron is released inside the cell. NO, ROS, and RNOS can react with labile iron–sulfur centers to regulate the mitochondrial tricarboxylic acid cycle enzyme aconitase. This enzyme participates in fueling the electron transport chain, and its inhibition would lower cellular ATP production. Furthermore, cytosolic aconitase, a regulator of intracellular iron levels, is similarly modulated by NO and redox mechanisms. This enzyme is identical to iron regulatory protein-1 (IRP-1), formerly known as an iron-response element-binding protein (IRE-BP). IRP-1 regulates the expression of key proteins involved in iron homeostasis such as ferritin and transferrin. Low intracellular iron triggers the binding of IRP-1 to iron-responsive elements (IREs) in mRNAs encoding ferritin and transferrin receptor. Excess NO can also increase the IRP-1/IRE complex formation and increase iron uptake into the cell, while abolishing the aconitase activity of IRP-1. NO can also bind to transferrin receptors and cause iron loss from ferritin and further increase the levels of free cytotoxic intracellular iron. IRP-1 is also targeted by peroxynitrite, which irreversibly inhibits the aconitase activity and the binding of IRP-1 to IRE, thus decreasing the iron uptake into the cell. It is possible that IRP-1-like proteins may be redox signaling regulators, and depending on local conditions, they may transduce NO or metal signals into gene expression. The biological effects of NO or peroxynitrite action on iron homeostasis can lead either to cytotoxicity owing to elevated free intracellular iron or to cytostasis owing to decreased intracellular iron, respectively. Moreover, cellular damage produced by oxidative and nitrosative stress may lead to activation of cellular proteases and nucleases and further damage the cells. Depletion of energy sources by nitrosative damage to the mitochondrial electron transport chain complexes I (NADH:ubiquinone oxidoreductase) and II (succinate:ubiquinone oxidoreductase), and by activation of poly(ADP-ribosyl) polymerase (PARP), also known as poly(ADP-ribosyl) synthetase (PARS), which supports high-energy phosphate metabolism, results in extensive cell injury and death. Consequently, the NO-mediated cytotoxicity is both beneficial and detrimental to the host in the sense that it destroys tumors or pathogens but also causes inflammation, cytokine-induced hypotension, immunosuppression, and carcinogenesis (Table IV).

As shown earlier in this chapter, the majority of NO-mediated cytotoxic effects are indirectly produced via NO interaction with ROS. Hydrogen peroxide (H_2O_2) and NO may affect the cellular redox balance, and their interaction may potentiate each other's cytotoxic effects. Cells that are resistant to H_2O_2 seem to be unaffected by the toxic effects of NO. H_2O_2 cytotoxicity is enhanced by the fact that NO inhibits catalase activity. Likewise, decreased intracellular levels of glutathione, glutathione peroxidase, and metallothionein enhance the cytotoxicity of both, NO and H_2O_2 .

**Table III Enzymes Inhibited
by S-Nitrosylation**

Alcohol dehydrogenase
Aldehyde dehydrogenase
Aldolase
Calpain
Cathepsin B
Creatine kinase
Cysteine proteases
Cytochrome P-450 aromatase
DNA repair enzymes (see Fig. 2)
Ecto-5'-nucleotidase
Glutathione peroxidase
Glutathione reductase
Glyceraldehyde-3-phosphate dehydrogenase (GAPDH)
Methionine synthase
NADPH oxidase (assembly but not activity)
Ornithine decarboxylase (ODC)
Phosphotyrosine protein phosphatase
Protein kinase C
Zinc finger motif DNA-binding enzymes
(DNA ligase, formamidopyrimidine DNA-glycolase)

Table IV Cytotoxic Effects of NO and/or RNOS^a

Antioxidant depletion → ascorbate and glutathione scavenging

Modulation of action of ROS, RNOS, toxic metals, and alkylating agents

Nitrosation of amines → nitrosamines

Key enzymes inactivated by S-nitrosylation: see Table III

Other proteins affected by S-nitrosylation include actin, albumin, activator protein 1 (AP-1), DNA methyltransferases, glutathione, G proteins, NF-κB, protein kinase C, and tissue plasminogen activator (tPA)

Poly(ADP-ribose) synthetase/polymerase deregulation (PARS/PARP) → depletion of cellular energy sources

NAD dehydrogenase → ↓ ADP ribosylation of GAPDH

↓ Alkyl transferases

↓ Iron–sulfur centers

NADH:ubiquinone oxidoreductase (mitochondrial electron transport chain complex I)

NADH:succinate oxidoreductase (mitochondrial electron transport chain complex II)

Regulates cytosolic aconitase/IRP-1 (iron regulator protein-1) and binding to IREs (iron response elements)

Mitochondrial *cis*-aconitase (tricarboxylic acid cycle), supports high energy phosphate metabolism

Ferrochelatase → ↓ heme

Ferritin

Ribonucleotide reductase → ↓ DNA synthesis

Cyclooxygenase 1, 2

Cytochrome P-450 → drug metabolism and therapeutic gain (reversible inhibition)

Cytochrome P-450 → heme release → heme oxygenase activation → heme hydrolysis → ↑ free iron (irreversible inhibition)

Ribonucleotide reductase → ↓ DNA synthesis

Nitric oxide synthase

Cyclic AMP responsive element-binding protein (CREB)

Cytochrome *c* oxidase → ↓ mitochondrial electron transport → respiration → energy depletion

Interacts with:

Fe²⁺ and free thiols → dinitrosyl–iron complex → depletes cellular iron (transport form of NO)

Transition metals → metal NO adducts

↑ Release of iron from ferritin and transferrin

↑ Free intracellular transition metal ions → activation of cellular proteases and nucleases → ↑ cell damage

↑ Free intracellular heavy metal ions

↑ Free intracellular calcium

DNA damage (see also Fig. 2)

↑ DNA deamination

↓ DNA binding proteins

↑ DNA/RNA strand breakage

↑ DNA alkylation

↓ DNA repair enzymes

↓ Ribonucleotide reductase → ↓ DNA synthesis

↑ DNA oxidation

↓ Zinc–sulfur centers (zinc fingers)

Other effects

↓ Membrane receptors

↓ Ion transporters

↑ Lipid peroxidation

↑ Inflammation

↑ Hypotension

↑ Immunosuppression

↑ Carcinogenesis

^aCytotoxic effects include direct and/or indirect reactions (oxidation, nitrosation, and nitration). GAPD, glyceraldehyde-3-phosphate dehydrogenase; ADP, adenosine diphosphate; ↑, increased activity; ↓, decreased activity.

CYTOPROTECTIVE ROLE OF NITRIC OXIDE

At the other end of the spectrum NO can act as an antioxidant or cytoprotector, and the resistance of certain cell types to NO-mediated cytotoxicity is due a complex and effective defense arsenal. Superoxide dismutase, catalase, glutathione peroxidase, metal storage proteins, heme, and hemoglobin, plus a number of free-radical scavengers such as ascorbate, tocopherol, and glutathione, are all part of the

cellular defense system, and NO is capable of influencing the activity of some of them. For example, intracellular glutathione has high affinity for RNOS, and its depletion markedly enhances NO cytotoxicity. Activator protein 1 (AP-1), a NO-controlled transcription factor, is the mediator of glutathione *S*-transferase expression. Additionally, NO may have a protective role by diverting O₂^{•−} away from iron–sulfur clusters toward sulfhydryl centers, preferred by ONOO[−].

NO is also able to rapidly bind metallo-oxo complexes (strong oxidants, containing high valent metal complexes, formed from oxidation of metals by ROS such as hydrogen peroxide), lower their valent state and therefore, reduce their cytotoxicity. Thus, by limiting the availability of iron, by preventing the cytotoxic effects of superoxide and hydrogen peroxide, NO plays another one of its cytoprotective roles. This may take place by inhibition of heme oxidation and attenuation of DNA and lipid peroxidation. Accordingly, NO-mediated antibacterial, antiparasitic, and tumoricidal effects are cytoprotective to the host during the normal acute immune response (Table V).

Direct Effects of Nitric Oxide

NO is able to react directly with metals and metal-containing proteins, with free radicals, and with lipid peroxidation products to produce a wide range of biological effects, some of them in physiological and others in pathophysiological conditions. The resulting biological actions of NO may be regulatory, cytoprotective, and/or cytotoxic, as shown earlier, and are illustrated in Tables IV, V, and VI and elsewhere in this book.

Nitric Oxide Effects on DNA

NO has been shown to damage DNA in bacteria and mammalian cells. Elevated NO, RNOS, and ROS are the cause of cellular nitrosative, oxidative, and nitrative stresses that can produce a number of nucleic acid modifications, such as cross-linking of purine and pyrimidine bases and single-strand breaks in RNA and DNA, leading to mutagenesis, cancer, or cell death (Fig. 2, Table IV). Additionally, RNOS can damage DNA by nitrosating an exocyclic amine group in the nucleic acid bases to form a primary nitrosamine, which on deamination results in conversion of bases and generation of the highly reactive hydroxyl radical. These products of nitrosative deamination are elevated in the cells treated with lipopolysaccharide (LPS), and inhibition of iNOS reverses their formation, suggesting that NO is a strong contributor to the oxidative and nitrosative DNA damage leading to mutagenesis and carcinogenesis. DNA is considerably more susceptible to the nitrosative damage during replication and transcription, when it is single stranded. A large number of point mutations that result in G:C to A:T transitions in p53 and retinoblastoma antioncogenes have been found in brain tumors, lymphomas, leukemias, and small-cell lung carcinomas. Deaminations of 5-methylcytosine to thymidine (G:C to T:A transversions) are seen in liver, lung, breast, and stomach cancers. Mutations at A:T base pairs were shown in esophageal cancer.

Furthermore, NO can modulate the action of other carcinogens, and it has been shown that nitrosamines produced by activated macrophages or hepatocytes can be converted to alkylating agents, which in the presence of NO cause additional DNA damage and perturb the normal function of DNA repair apparatus. NO inhibits DNA alkyl transferase

by S-nitrosation of critical sulfhydryl residues and thus potentiates the toxicity of the alkylating agents. NO also modifies structurally proteins containing zinc finger motifs, resulting in loss of protein function (Table III, Fig. 2). Many of these enzymes are involved in transcription, replication, restriction, or DNA repair, and the NO-mediated release of Zn^{2+} from their molecule leads to structural changes that permanently inactivate them. Ribonucleotide reductase represents a multiple NO responsive site, and the reactions of NO with tyrosyl radicals, iron centers, and/or thiol groups inhibit the activity of this enzyme. As a result, DNA synthesis is dramatically diminished, and this cytostatic effect of NO is useful in anticancer therapy. In addition, $ONOO^-$, $\cdot NO_2$, and $HO\cdot$ cause DNA single-strand breaks that trigger activation of the DNA repair enzyme PARP and result in NAD^+ substrate depletion, inhibition of glycolytic and electron transport pathways, and diminished ATP production. Depletion of cellular energy sources leads to a rapid cell destruction and death (Fig. 2).

Prior to investigating the role of NO in cancer it is important to review the biological and molecular changes occurring in normal cells that lead to cell transformation and malignancy, as well as the factors that contribute to these changes.

Biological and Molecular Aspects of Carcinogenesis

Carcinogenesis is a multistep process starting with accumulation of mutations in somatic cells that alter cell morphology and growth patterns, leading to cell transformation, local invasion, and metastasis to distant sites. Environmental (chemicals, radiation, viruses) or hereditary factors are the cause of mutations that can result in malignant transformation. The main targets of mutagenesis are the growth promoting genes, growth inhibitory genes, and genes that control DNA repair and apoptosis.

Growth Promoting Genes (Proto-oncogenes)

Proto-oncogenes promote normal cell growth and differentiation (Fig. 3). The cell cycle starts with binding of a growth factor to its receptor on the cell membrane. This triggers a chain of events that leads to activation of the cell surface receptors, the inner membrane signaling proteins, and the cytosolic signal transduction pathways. The result is induction of nuclear factors that regulate DNA transcription, translation, and cell division. Additionally, a group of proteins known as cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors (CDKIs), modulate reentry of resting cells into the cell cycle and the progression through the cell-cycle phases. The genes encoding the proteins responsible for each of these steps can be targeted by mutagenesis. Proto-oncogenes transformation into oncogenes takes place via structural and regulatory changes that result in accumulation of multiple abnormal genes producing inappropriate amounts of growth-stimulating protein (Fig. 4).

Table V Cytoprotective Effects of Nitric Oxide^a

Antibacterial
Antiparasitic
Tumoricidal
↓ DNA synthesis by inactivating ribonucleotide reductase → ↑ tumor sensitization in radiation therapy
↓ DNA damage by Fenton reaction products
↓ Oxidative damage by hydroxylation
↓ Lipid peroxidation by reaction with:
Hydroxylperoxyl radical in atherosclerosis
Hydroxylperoxyl radical in lipoxygenase (NO also binds the nonheme iron at the active site)
ROS, copper ions
↓ Rapid binding of metallo-oxo complexes and reduction of high valent metal toxicity
↓ Iron availability by:
↓ Ferrochelatase (places iron in the porphyrinic ring) → ↓ Heme availability, ↓ NOS
Modulating iron uptake in transferrin receptor
Modulating iron storage in ferritin protein
↓ Iron regulatory protein-1 (IRP-1)
↑ Binding of IRP-1 to iron regulatory elements (IREs)
↓ Iron release from ferritin by preventing NADPH oxidase assembly
Peroxynitrite formation inhibits IRP-1 and binding of IRP-1 to IREs → ↓ iron uptake → ↓ oxidative stress
↓ Cytochrome <i>c</i> oxidase and electron flow in the mitochondria → ↓ ROS
Antioxidant (interacts with the cell defense mechanisms)
Free radical scavengers (ascorbate, tocopherols, glutathione)
Superoxide dismutase (SOD)
↓ Catalase
Glutathione peroxidase
Glutathione <i>S</i> -transferase (AP-1 mediated under NO control)
Glucose-6-phosphate dehydrogenase (G6PD)
Prevents dexamethasone-induced apoptosis
↓ Leukocyte adhesion and platelet aggregation and adhesion
↑ Bcl-2 via a cGMP-dependent mechanism
Diverts superoxide away from iron–sulfur centers toward sulfhydryl molecules preferred by peroxynitrite
Protects against H ₂ O ₂ toxicity by inhibiting aconitase
Protects against TNF- α and IFN- γ toxicity
Protects cytokine-depleted eosinophils in peripheral blood by a cGMP-dependent mechanism
Heme-containing proteins:
↑ Cyclooxygenases 1, 2
↑ Soluble guanylate cyclase
↓ Catalase
↓ Cyclooxygenases 1, 2
↓ Nitric oxide synthase
↓ Oxyhemoglobin → methemoglobin
↓ Oxy-myoglobin → metmyoglobin
↓ Peroxidase
Reacts with thiols → <i>S</i> -nitrosothiols
↓ Neutrophil NADPH oxidase (limits superoxide production)
↓ Vascular tone (activates soluble guanylate cyclase and calcium activated potassium channels)
Activates protein kinase signaling in activated macrophages

^a ↑, increased activity; ↓, decreased activity; ROS, reactive oxygen species; NOS, nitric oxide synthase; TNF- α , tumor necrosis factor α ; IFN- γ , γ -interferon.

Oncogenes are cancer causing genes derived from proto-oncogenes. Oncogenes encode oncoproteins, which are no longer able to respond to growth factors or other external signals during the cell cycle. Mutations in the proto-

oncogenes that encode growth factors, growth factors receptors, and signaling proteins may ultimately lead to continuous delivery of mitogenic signals to the cells and have been associated with various types of cancers.

Table VI Nitric Oxide Effects on Heme-Containing Proteins^a

Activates
↑ Cyclooxygenases 1, 2
↑ Soluble guanylate cyclase
Inactivates
↓ Catalase
↓ Cyclooxygenases 1, 2
↓ Cytochrome P-450
↓ Cytochrome <i>c</i> oxidase
↓ Heme oxygenase
↓ Indoleamine 2,3-dioxygenase
↓ Nitric oxide synthase
↓ Oxyhemoglobin → methemoglobin (NO inactivation in circulation)
↓ Oxy-myoglobin → metmyoglobin (NO inactivation in circulation)
↓ Peroxidase

^a ↑, increased activity; ↓, decreased activity.

Nuclear regulatory proteins of growth-related genes are the product of a family of oncogenes (*myc*, *myb*, *jun*, and *fos*) that when mutated are associated with malignancy.

Growth Inhibitory Genes

Growth inhibitory genes (antioncogenes, tumor suppressor genes) regulate multiple cellular events, and their products have different intracellular locations. Some are present in the nucleus (p53, Rb, p16, BRCA-1, BRCA-2, WT-1). APC is cytosolic, NF-1 and -2 are located in the inner plasma membrane and cytoskeleton, respectively, and transforming growth factor β (TGF- β) receptors are situated on the cell surface. All antioncogenes generate products that regulate cell proliferation. Antioncogenes associated with cancers undergo mutations of both alleles (loss of heterozygosity) and are known as recessive cancer genes. These genes are activated by extracellular growth inhibitors, which trigger the activation of a signaling pathway similar to that of proto-oncogenes.

The p53 gene is a nuclear phosphoprotein that regulates multiple cellular processes, including DNA transcription, DNA repair, angiogenesis, tumor progression, invasiveness and metastasis, genomic stability, cell cycle, senescence, and cell death. This gene has a half-life of several minutes and is not required for normal cell proliferation. p53 loss of heterozygosity is found in the majority of colon, breast, and lung cancers, and also in leukemias, sarcomas, and neurogenic tumors. Exposure to mutagens leads to p53 stabilization and accumulation into the nucleus, where it binds to DNA and arrests the cell cycle in G₁ phase, allowing the cell time to repair the damaged DNA. If the repair mechanism fails, the p53 triggers the apoptotic mechanism to kill that cell.

Consequently, loss of normal p53 function allows the damaged DNA to be replicated and to permanently add the mutations to the genome. Cumulative addition of mutations to the genome, as a result of loss of p53 pathway ac-

tivity, may ultimately lead to malignant transformation. Transforming proteins of DNA viruses (Table XIV) can also bind and sequester both normal p53 and Rb genes and further increase the risk of malignancy. Additionally, p53 has the ability to function both as an oncogene and antioncogene, owing to the fact that a single-allele mutation in p53 can bind and inactivate normal p53 protein. Functional inactivation of p53 occurs in the majority of human cancers and also in the tumor resistance to the DNA-damaging effects of chemotherapy and radiation therapy.

Mutations in the Rb gene, produce retinoblastoma in children. The Rb gene product, pRB, is an omnipresent nuclear phosphoprotein that regulates the cell cycle. Mutations in the Rb gene generally affect the regulation by the transcription factor-binding domain that leads to erratic cycling and malignant transformation.

DNA Repair Regulatory Genes

Genes that regulate the repair of damaged DNA and affect indirectly cell proliferation, include proto-oncogenes, antioncogenes, and apoptosis-regulating genes. The DNA repair regulatory genes are not oncogenic by themselves, but they allow replication errors in other genes to become permanent (Fig. 2).

Cyclins and Cyclin-Dependent Genes

Cyclins and CDKs mediate the return of resting cells to the cell cycle and ensure progression through the cell cycle phases (Fig. 3). CDKs are constitutively expressed and become activated by phosphorylation after binding to the cyclins induced during the cell cycle. CDKs are grouped in two families: broad-spectrum inhibitors (p21, p27, p57) and specific inhibitors (p15, p16, p18, p19). Overexpression of cyclin D has been shown in cancers of the esophagus, breast, and liver and in some lymphomas. Amplification of the CDK4 gene is present in melanomas, sarcomas, and glioblastomas.

Mechanism of Carcinogenesis and Tumor Progression

Tumors contain two basic tissue components: parenchyma, which consists of proliferating neoplastic cells, and supportive stroma that includes extracellular matrix (ECM) components and blood vessels. There are several stages of cellular changes that lead to malignancy: (A) transformation of normal cells, (B) growth of the transformed cells, (C) angiogenesis, (D) local invasion, and (E) metastasis to distant sites.

Transformation of Normal Cells

Transformation of normal cells is the result of accumulation of mutations that produce activation of multiple onco-

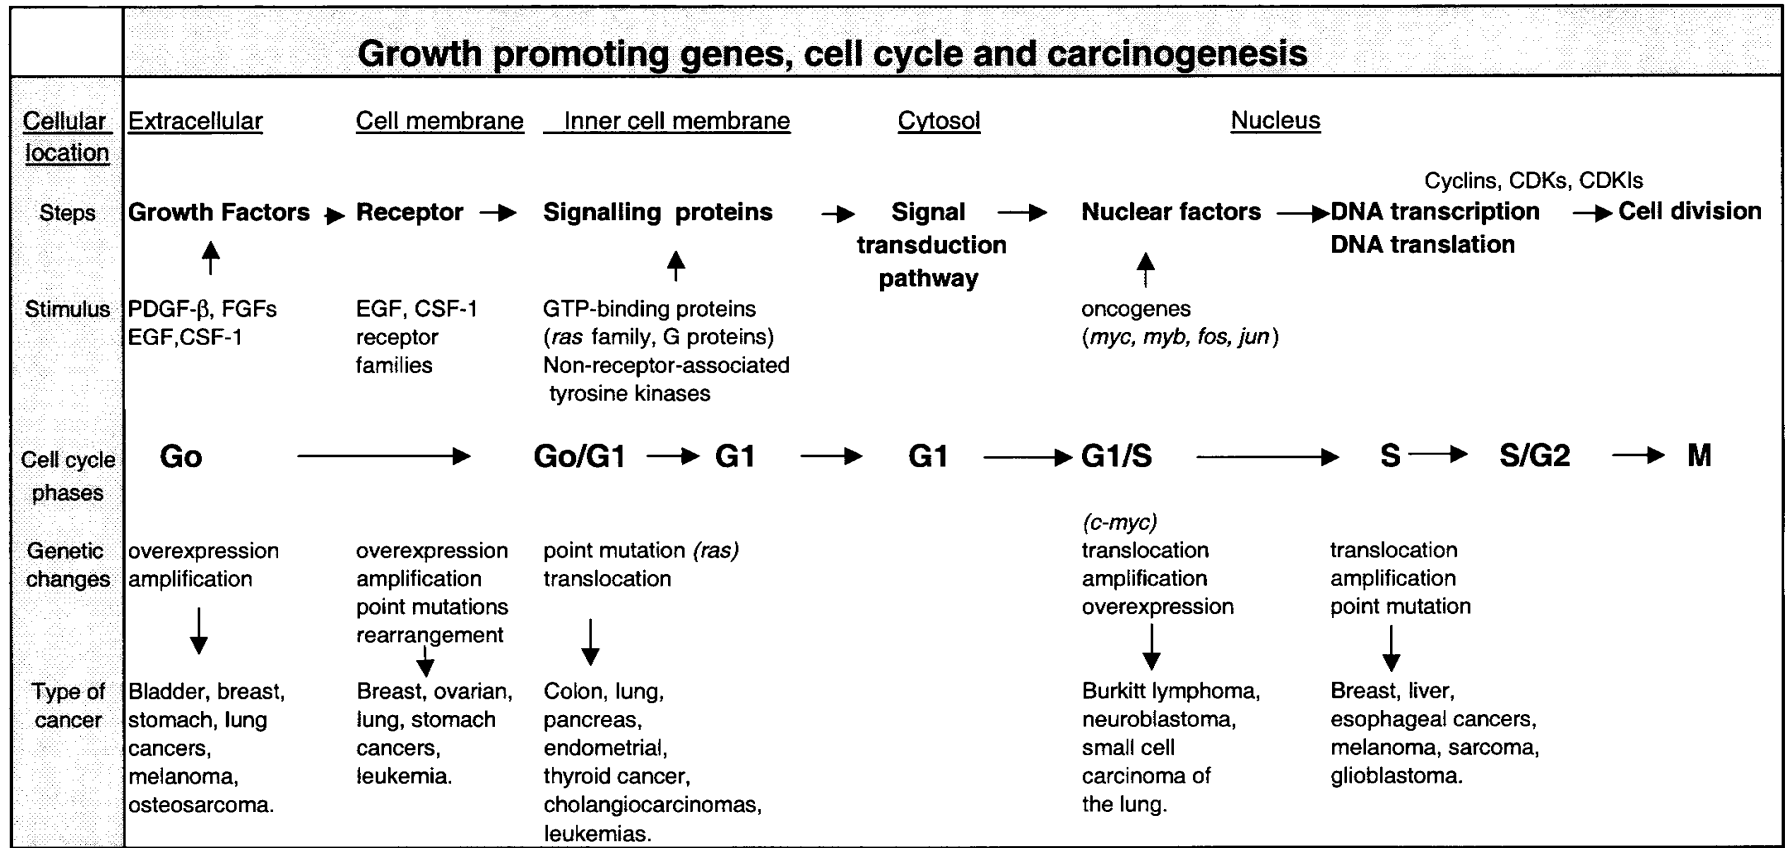

Figure 3 Schematic illustration of the sequence of events that take place in proto-oncogenes following growth factor stimulation, and the biological effects occurring after alterations in the growth factor signaling pathways during the cell cycle. PDGF = platelet-derived growth factor, FGFs = fibroblast growth factors, EGF = epithelial growth factor, CSF-1 = colony stimulating factor-1, CDKs = cyclin-dependent kinases, CDKIs = cyclin-dependent kinase inhibitors.

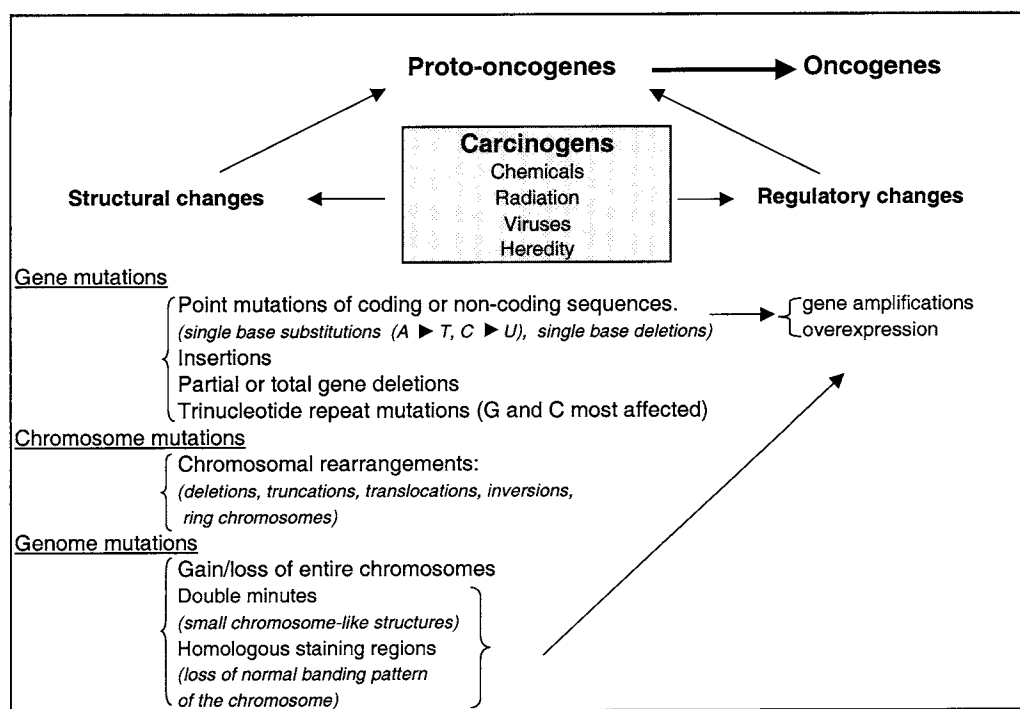

Figure 4 Proposed role of carcinogens in transformation of proto-oncogenes into oncogenes. A = adenine, T = thymine, U = uracil, C = cytosine, G = guanine.

genes and inactivation or loss of multiple antioncogenes and DNA repair and apoptosis genes. The genetic changes that lead to cell transformation may be as discreet as the point mutations, or as pronounced as the gain or loss of entire chromosomes (Figs. 2–4) and may provide important diagnostic information.

Growth of Transformed Cells

The growth of transformed cells is influenced by a number of tumor and host factors that ultimately determine tumor characteristics such as differentiation level, cell kinetics, progression, and cytological heterogeneity.

1. An important factor in determining the malignancy of tumors is cell differentiation level. Malignant tumor cells vary from well differentiated, moderately well differentiated to poorly differentiated, or undifferentiated (anaplastic). Well-differentiated tumor cells retain the morphology and most of the functions of their normal counterparts, whereas the anaplastic cells become morphofunctionally simplified and resemble each other regardless of their original source. As a result, a tumor grading system was designed to express the level of differentiation of tumor cells. Cancers are classified as grades I–IV with increasing anaplasia. The staging (I–IV) of cancers defines the size of the primary tumor and the level of spreading to regional lymph nodes as well as the presence or absence of metastases.

2. Cell cycle, growth fraction, and progressive growth are characteristics that define the tumor cell kinetics. The

tumor cell cycle contains the same phases that are present in the normal cells, and the total cycle time is essentially the same. What differentiates the tumor from the normal tissues is the proportion of proliferating cells in the tumor (the growth fraction). In the early stages of tumor growth the majority of transformed cells are proliferating, whereas in later stages the cell proliferation is dramatically attenuated and cells are lost to shedding, differentiation, or reversal to G_0 phase. Thus, by the time the tumor is detected the majority of cells are no longer replicating and this constitutes one of the main reasons for the high failure rate of anticancer therapy. The imbalance between cell production and cell loss, which represents the progressive growth of a tumor, is high in rapidly growing tumors, such as leukemias and lymphomas. In low-growth tumors such as in colon cancers, the cell production slightly exceeds cell loss.

3. Tumor progression from preneoplastic lesions, to benign tumors, to invasive malignancies, to metastatic tumors, attests the increasing aggressivity of tumors over time. This is owed to formation of heterogeneous tumor subpopulations that are different in their rate of growth, invasiveness, metastatic dissemination, and responsiveness to hormones and drugs. Consequently, despite the fact that most cancers are monoclonal in origin, by the time they become clinically evident, their cell population is highly heterogeneous as a result of multiple mutations accumulated in different cells and their subsequent subclonal characteristics. Host immune activity may destroy some of the highly antigenic tumor cells and allow only slower growing cells to survive (Fig. 6). Ultimately, a growing tumor is populated with highly resistant

Table VII Cellular Events That Occur in Angiogenesis^a

1. Angiogenic stimulus (TGF- α and - β , leptin, EGF, PDGF, hypoxia)
2. Basement membrane degradation
3. Secretion of angiogenic factors
4. Sprouting and migration into extracellular matrix
5. Endothelial cell proliferation (VEGF+VEGF-R2)
6. Endothelial cell maturation
7. Development of capillary lumen (VEGF+VEGF-R1)
8. Recruitment of pericytes and smooth muscle cells
9. Secretion of growth inhibitors (Ang 2/Tie-2)

^aAbbreviations: VEGF, vascular endothelium growth factor; VEGF-R, vascular endothelium growth factor receptors; PDGF, platelet-derived growth factor; EGF, epithelial growth factor; TGF, transforming growth factor; Ang/Tie, angiopoietin/angiopoietin receptor.

cells that are able to survive, proliferate, invade, and metastasize to distant sites.

Angiogenesis

Angiogenesis, or formation of new blood vessels by sprouting of new capillaries from existing vessels, is re-

quired for both tumor growth and metastasis. Angiogenesis occurs both physiologically in pregnancy and during the menstrual cycle, and pathologically in atherosclerosis, diabetes, and carcinogenesis. This process is triggered by a number of angiogenic factors, which can either be released from tumors, or can be induced in the surrounding cells by the tumor cells. Angiogenesis is regulated by endothelial tyrosine kinase receptors (Tables VII and VIII). Tumor growth is supported by the normal host cells, which are induced to form new capillaries around the tumor to provide adequate blood supply for metastatic dissemination. Conceivably, host endothelial cells and tumor cells closely interact and influence each other in multiple ways.

Local Invasion

Local invasion is an exclusive characteristic of malignant cells, which have the ability to infiltrate and invade surrounding tissue. Invasion of ECM, is both an active process, involving the detachment of tumor cells from each other, attachment to ECM components, degradation of ECM, and migration, and a passive process due to cell growth. Serine and cysteine proteinases and matrix metalloproteinases (MMPs, also known as collagenases or gelatinases), are active during the early stages of tumor invasion. They are

Table VIII Angiogenic Factors^a

Ligand	Receptor
Tumor-derived	(Endothelial tyrosine kinases)
VEGFs	VEGF-R1, -R2, -R3
Angiopoietins (Ang-1, Ang-2)	Tie-1, Tie-2
β -FGF	
PDGF	
EGF	
TGF- α and - β	
Tumor-induced	
Angiogenic factors (in infiltrated inflammatory cells)	
β -FGF, induced by tumor TGF- β	
TNF- α , induced by tumor TGF- β	
Antiangiogenic factors	
Thrombospondin-1 (can be also tumor-derived)	
Endostatin	
Angiostatin	
Vasculostatin	
Other angiogenic factors	
Neuronal guidance proteins	Neuropilin
Ephrin (Eph)	Eph B2, Eph B4
Leptin	Leptin receptors
Regulators of angiogenesis	
Integrins	
Thrombospondin-1 via p53 (see Table IX)	
Interferons	
Proteases (plasminogen activators, MMPs)	

^aAbbreviations: VEGF, vascular endothelium growth factor; VEGF-R, vascular endothelium growth factor receptors; β -FGF, fibroblast growth factor; TNF- α , tumor necrosis factor; PDGF, platelet-derived growth factor; EGF, epithelial growth factor; TGF, transforming growth factor.

released either directly from the tumor cells or by the surrounding fibroblasts. The tumor proteolytic activity generates cleavage products of a number of ECM components, which together with some tissue-derived factors have chemotactic, angiogenic, and growth stimulating effects on tumor cells, and may play a role in organ-selective homing of tumor cells.

Metastasis

Metastasis is a multistep, interactive process between the malignant tumor cells and the host cells. Primary tumors and their metastases contain multiple cell types that are capable to resist the host immune attack and anticancer treatment by modulating their microenvironment to their advantage. As shown earlier, tumor biological diversity includes differences in growth pattern, cell deformability, surface receptors and adhesion molecules, immunogenicity, and karyotype. Other factors include the ability to form aggregates (emboli) with other tumor cells and/or lymphocytes and platelets to induce hemostasis and the ability to invade their surrounding tissue. Metastasis can occur by lymphatic, vascular, or direct dissemination. Lymphatic dissemination is conceivably the preferred route for carcinomas and sarcomas. Local lymph nodes are the first to be involved in metastasis, and also represent the first stop where tumor cells are exposed to the host immune attack. Enlargement of local lymph nodes is the result of both tumor cell proliferation and the reactive hyperplasia of the host tissue. Venous dissemination is used by sarcomas and some carcinomas penetrating the thinner walls, to follow the venous blood to the liver and lungs, a second stop in metastasis. Arterial dissemination, via pulmonary capillaries, involves mostly lung metastases. During vascular dissemination tumor cells are exposed to a variety of host factors such as local hemodynamics and the immune attack. The action of the activated macrophages and natural killer (NK) cells plays a key role in the destruction of circulating tumor cells. At this stage tumor cells tend to aggregate in homotypic (tumor cells only) or heterotypic (tumor cells and platelets or immune cells) emboli. Heterotypic aggregation with platelets enhances the tumor ability to survive and attach to the blood vessel wall and to penetrate it (extravasation), during a process that again involves the interaction between the host ECM and the tumor adhesion molecules, receptors, and proteinases. Conceivably the vast majority of tumor cells that enter circulation die and only a small, highly specialized subpopulation of cells originating in the primary tumor cells are capable of producing metastases. This cycle, if it is not interrupted by anticancer therapy, continues until the function of most of the host vital organs is compromised.

Organ tropism represents the site at which tumor cells extravasate. Adhesion molecules present on the tumor cell surface may prefer the ligands on the endothelium of certain organs, which may secrete either chemoattractants to recruit certain tumor cells or antiproteases that may prevent tumor metastasis.

Is Nitric Oxide Tumorigenic or Tumoricidal?

Tumoricidal or tumorigenic actions of NO are highly dependent on the conditions in the tumor microenvironment. A number of experimental and clinical examples confirm the duality of the cellular effects of NO and the significance of other factors independent of NO that may ultimately determine its biological role at any given time.

Tumorigenic Actions of Nitric Oxide

The nitric oxide concentration in tumors seems to be an important factor in carcinogenesis, and a number of studies have shown that high NO levels are tumoricidal, whereas low NO levels are tumorigenic (Figs. 2 and 5, Table IV). Some cancers are less susceptible to the toxic effects of NO, and in these types NO can actually stimulate their growth by promoting angiogenesis and tumor cell proliferation. Most experimental solid tumors were shown to have increased expression of iNOS, and with NO being both angiogenic and genotoxic, its increased production may contribute to carcinogenesis. Additionally, NO generated in tumors increases vascular permeability, which enhances nutritional supply and sustains the rapid growth of tumor cells. Inflammatory responses induced by various pathogens can accelerate tissue damage and mutagenesis, and NO may effectively sustain the growth of the transformed cells.

The cytostatic effects of NO seem to occur predominantly in tumor cells containing a functional wild type of p53 anti-oncogene. As shown earlier tumor cells with missing or mutated p53 show posttranslational modifications in p53, a preinvasive feature evident in cancers resistant to NO-mediated apoptosis such as, breast, esophageal, and bronchial cancers. Therefore, in the presence of low NO levels these tumors are capable of rapid growth. Elevated NO causes DNA damage and apoptosis in many cell types. A variety of genetic and physiological data indicate that p53 is an important negative feedback regulator of excessive NO production *in vivo*. NO induces p53 accumulation and as part of a feedback mechanism, it mediates the transcriptional transrepression of iNOS. p53-deficient mice, prone to spontaneous tumorigenesis, excrete 70% more nitrite and nitrate than wild-type p53 mice.

The role of NO and estrogens in breast cancer is still unclear, although the balance tends to lean toward a procarcinogenic action. In combination with a NO donor agent, a catechol-estrogen was shown to synergistically induce DNA strand breakage. The DNA damage was much more pronounced than the one produced by each substance alone. These effects were inhibited by NO-trapping agents and by antioxidants. Both NO and catechol-estrogen are formed in the human breast and uterine tissues, and their synergism generates potent ROS that may be involved in hormone-induced carcinogenesis. Similarly, cNOS has been shown to be present in various human tumor cell lines such as neuroblastoma, cervix carcinoma, and breast cancer cells, where it

correlates strongly with the expression of estrogen receptor. Selective iNOS inhibition of *in vivo* growth of murine mammary adenocarcinoma cells expressing iNOS, resulted in a significant reduction of tumor weight as compared to that of controls, suggesting a definite role for NO in tumorigenesis in this type of cancer. Inhibition of iNOS in a murine colon adenocarcinoma, containing an increased number of intratumoral macrophages as the main source of NO, did not affect tumor growth or plasma NO levels. All of these examples suggest that NO production in the tumor microenvironment plays a key role in promoting tumor growth in certain cancers, and that the host defense mechanism is often ineffective in inhibiting tumor growth in these types of cancer.

It is also possible that the majority of tumor cells containing high NO levels undergo autolysis, and only the NO resistant ones survive. These tumor cells are then able to generate and use NO to their advantage and promote tumor progression and metastasis. Such cells have been shown to exist in a number of human cancers of CNS, breast, gynecological (ovarian, mixed mesodermal, and endometrial) cancers, and in murine colon, or mammary adenocarcinomas. Furthermore, in some cancers only the poorly differentiated tumors produce NO, which is absent in the normal surrounding tissues. In other tumors both the infiltrating macrophages and the vascular cells become activated by the tumor-generated cytokines and produce low NO levels. In all these cancers NO is a facilitator of tumor growth by maintaining optimum blood flow and pH, by limiting leukocyte–endothelial cell interactions, and by increasing vascular permeability (Fig. 5). Inhibition of iNOS effectively reverses the tumorigenic effects of NO in this type of cancers.

Tumoricidal Actions of NO

The antitumor activity of NO includes inhibition of tumor cell proliferation, promotion of cell differentiation, and reduction of the metastatic spread (Fig. 5 and Table V). Tumoricidal effects of NO generated by macrophages was demonstrated soon after the identification of endothelium-derived relaxing factor (EDRF) as NO. Macrophages activated with LPS and γ -interferon (IFN- γ) were shown to cause specific injuries to the iron–sulfur clusters present in complex I and II enzymes of the mitochondrial electron transport chain, and to inhibit DNA synthesis and mitochondrial respiration. These effects were inhibited by superoxide or by reduced myoglobin, agents that inactivate NO. High NO levels are generally tumoricidal and this is of particular significance as a therapeutic approach that can be used in tumors susceptible to NO-mediated apoptosis. For example, iNOS overexpression in murine melanoma cells was shown to inhibit tumor growth and survival, both *in vitro* and *in vivo*. Relaxin, a peptide hormone produced in the ovary, inhibits growth and promotes differentiation of breast adenocarcinoma cells and also stimulates NO production. These observations suggest that the cytostatic effect of relaxin on breast tumor cells may be mediated by the increased NO production. Similarly prolonged administration of sodium nitroprusside significantly decreased the incidence of gastric cancers, without affecting the morphology of the lesions. This inhibitory effect is presumed to be due to the suppression of cell proliferation in the gastric epithelial cells by NO. Bacillus Calmette-Guerin (BCG) has been used for years in the treatment of urinary bladder cancer. There is both *in vivo*

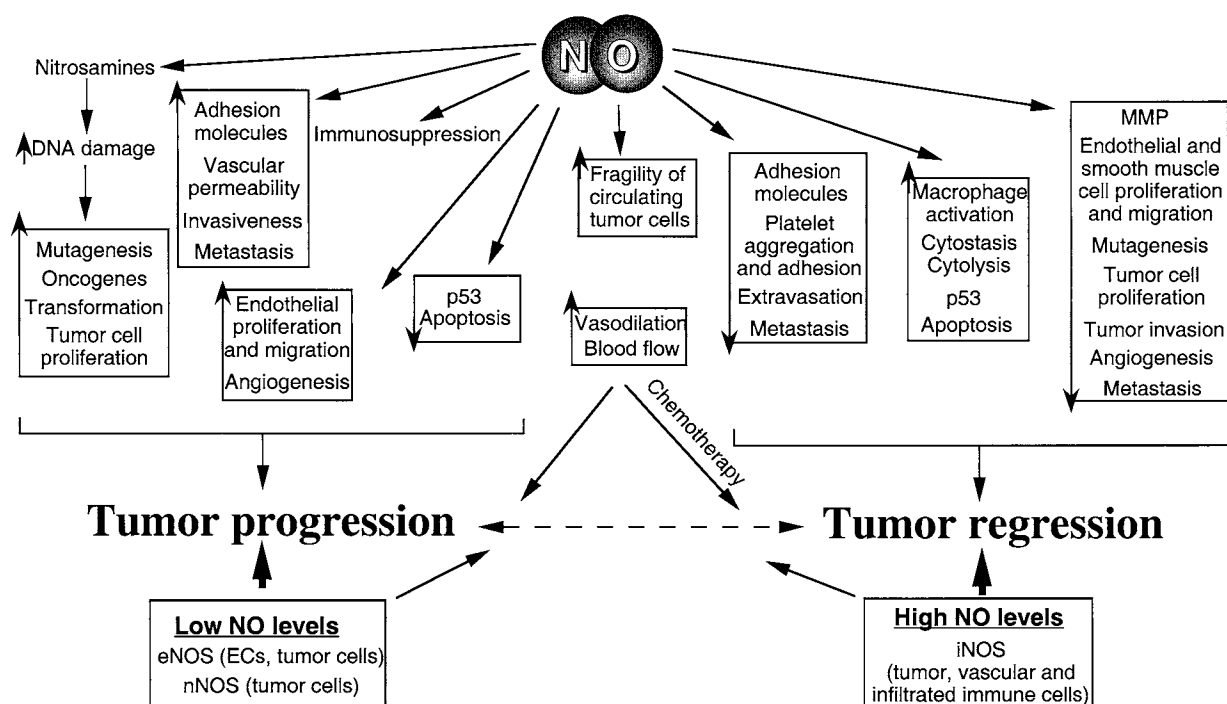

Figure 5 Cellular events mediated by NO and tumor development.

and *in vitro* evidence indicating that elevated NO generated following the treatment with BCG exerts cytotoxic effects on the urinary bladder tumor cells. These findings suggest that NO synthesis during the immune-mediated response to BCG may be an important factor in BCG-mediated anticancer therapy.

The main effector cells responsible for the early anti-tumor defense are NK cells and macrophages (Fig. 6). Depletion of NK cells or iNOS inhibition decreased the tumoricidal activity of tumor-associated macrophages in a melanoma cell line. Additionally iNOS inhibition accelerated the growth of inoculated melanoma cells and this effect was reversed by administration of IFN- γ . The cytostatic and cytotoxic activity of macrophages is in part attributed to the production of NO as a result of NOS induction. The intensity of iNOS expression in alveolar macrophages was shown to be positively correlated with the levels of exhaled NO in patients with primary lung cancer as compared to control subjects.

In addition to NO, its precursors L-arginine and *N*^G-hydroxy-L-arginine (NOHA), along with polyamines, may participate in the regulation of carcinogenesis. L-Arginine is a substrate for both NOS and arginase, one of the urea cycle enzymes that has been found in hepatocytes and in a number of other cell types. Arginase can be present constitutively (arginase I) or it can be induced (arginase II) by LPS, cAMP, and some cytokines to convert L-arginine into L-ornithine and urea. L-Ornithine is the substrate for ornithine decarboxylase (ODC) a short-lived enzyme which decarboxylates ornithine to produce the diamine putrescine, the precursor of the polyamines spermidine and spermine, molecules that play a critical role in cell proliferation. ODC is the rate-limiting enzyme in the synthesis of polyamines, and more recently it was shown that both arginase and ODC can be modulated by NOS reaction products. Increased arginase expression and elevated levels of putrescine have been found in tumor cells and inhibition of one or both urea cycle enzymes (arginase and ODC) inhibited tumor development. Thus, two sequential products of NOS activity, NOHA and NO, inhibit two sequential enzymes in the urea cycle. NOHA is a potent inhibitor of arginase, whereas NO inhibits ODC activity by S-nitrosylation (Table III). Additionally, polyamines have both a proliferative effect on tumor cells and an angiogenic effect on vascular cells. Therefore, modulation of the polyamine pathway may be of critical importance in cancer.

Nitric Oxide and Chronic Inflammation

NO has long been shown to inhibit the growth of bacteria, fungi, and parasites by reacting with key sulfhydryl groups in glycolytic enzymes, ferredoxins, or hydrogenases, and consequently it plays a role in host defense mechanisms. This is important considering that chronic exposure to high levels of NO, ROS, and RNOS, commonly present at chronic infection and inflammation sites, may subsequently lead to carcinogenesis. For example, gastric cancers often

occur in patients suffering from chronic atrophic gastritis. *Helicobacter pylori* infected patients, may have an increased risk of developing gastric cancer due to bacterial-induced chronic inflammation and also due to ingestion of dietary nitrosamine precursors in the acidic nitrosating conditions in the stomach. Furthermore, chronic heartburn, known medically as gastroesophageal reflux disease (GERD), can considerably increase the risk of developing adenocarcinoma of the esophagus, one of the deadliest forms of cancer. Similarly, colon cancer is frequently present in patients with ulcerative colitis. Hepatocellular carcinoma develops in patients suffering from chronic hepatitis and cirrhosis. Gallbladder carcinoma may occur in patients with gallstones and chronic cholecystitis. Chronic infection with liver fluke is accompanied by prolonged elevation of NO in the plasma, saliva, and urine of infected patients or experimental animals and it strongly correlates with the development of cholangiocarcinoma. Additionally, nitrosamines formed endogenously from dietary precursors are potential risk factors for the development of cholangiocarcinoma and hepatocellular carcinoma in patients infected with liver flukes and cirrhosis, respectively. There is a strong correlation between infection with hepatitis C virus, NOS induction, upregulation of p21 (see earlier), and the development of hepatocellular carcinoma.

Nitric Oxide and Metastasis

Metastatic dissemination represents the main cause of death in cancer patients, as an ongoing war ensues between the invading tumor cells, the host defense arsenal, and the anticancer therapy. Resistance to therapy is caused by the aforementioned factors (see earlier) that facilitate the survival and growth of tumor cells. Moreover, other determinants including late detection of primary tumor and the spreading of metastases beyond the local lymph nodes, tumor inaccessibility to surgery or to conventional anticancer therapy, are all due to the tumor cytological heterogeneity. As mentioned earlier, tumors contain multiple cell subpopulation clones of the original transformed cell that are capable to survive the host immune attack and are able to resist treatment by modulating their milieu to their advantage. Tumor resistance to drugs is a significant contributor to the high failure rate of current anticancer therapy.

PROMETASTATIC ROLE OF NITRIC OXIDE

Tumor progression and metastasis can be impacted positively or negatively by the presence of NO, and studies propose a dual role for NO in tumor biology. High NO concentrations possess tumoricidal actions, whereas lower NO concentrations supposedly promote tumor growth. A number of human cancers including breast cancer, colorectal adenocarcinomas, squamous cell carcinomas, glioblastomas, and meningiomas invariably express iNOS mRNA.

eNOS and iNOS activity is augmented in invasive breast tumors, as compared to normal or benign tissue. In human breast tumors NOS expression invariably correlates with

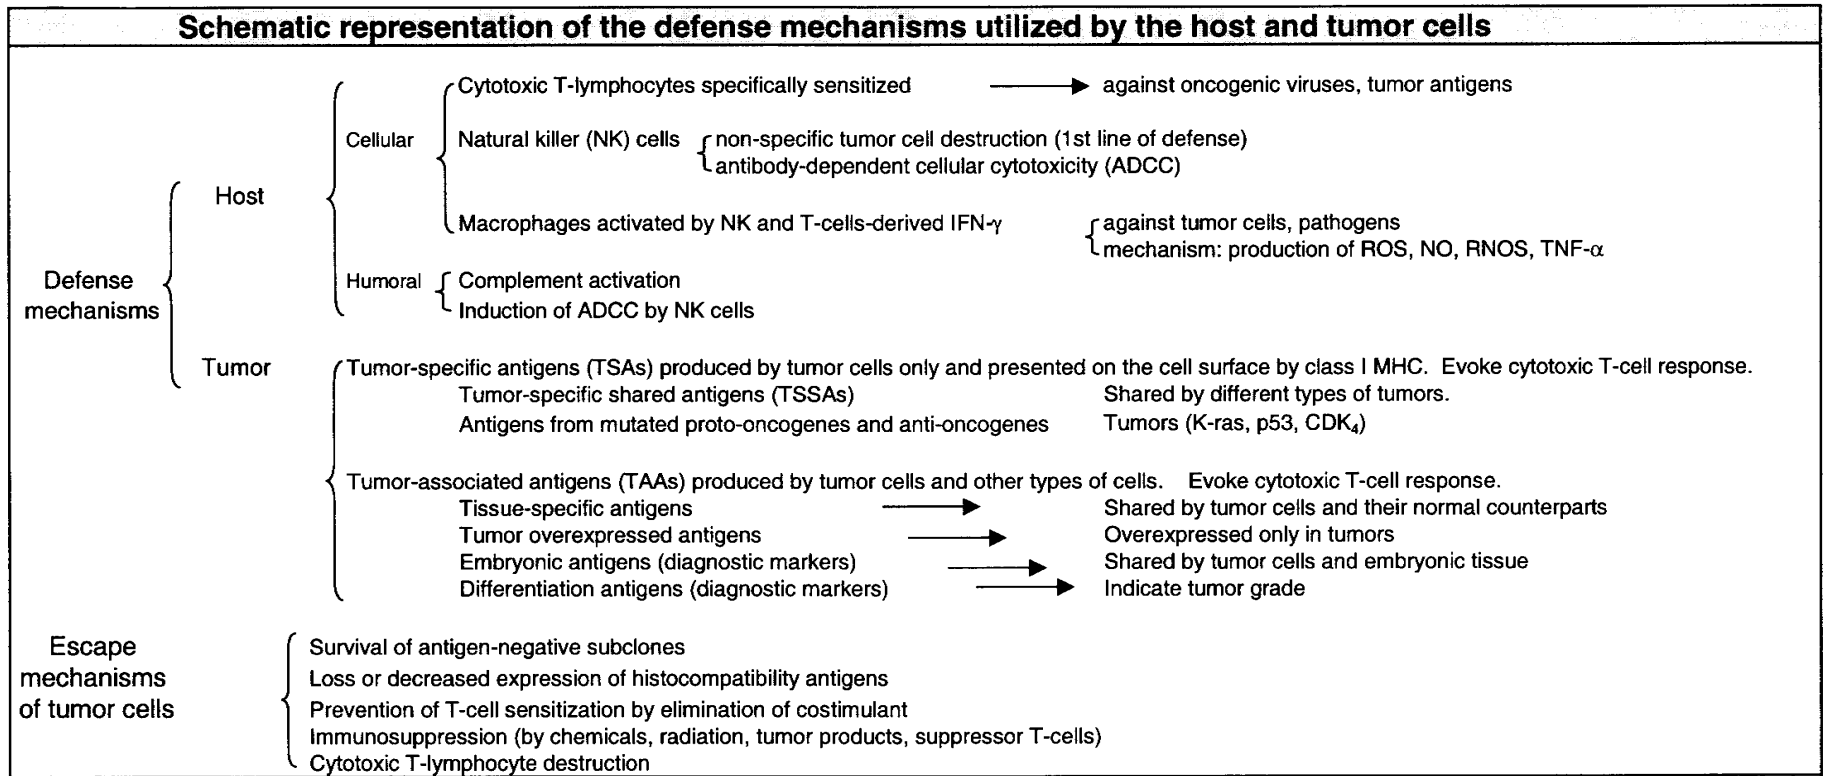

Figure 6 Schematic representation of the defense mechanisms utilized by the host and tumor cells.

tumor grade. For example, in invasive ductal carcinomas NO biosynthesis was significantly enhanced in grade III compared to grade II tumors, whereas NOS activity in cells harvested from primary and metastatic sites of patients with ovarian cancer was higher in the more differentiated tumors. Histological examination of the samples revealed an elevated macrophage content accompanied by high NOS activity. This further underlines the complexity of the relationship between tumor progression, NOS expression, and the immune response, indicating that the differentiated status of the tumor is only one of the multiple factors responsible for cancer progression. NO is presumed to be involved in the abnormal vascularization associated with tumorigenesis. There is a strong correlation between the presence of NOS and axillary lymph node metastasis and also between NOS and the absence of the antimetastatic gene nm23 markers, indicating a role for NO in the increased blood flow and metastasis. Breast cancer has the ability to metastasize rapidly and tumor vascularization is one of the factors contributing to increased metastasis (Fig. 5, Table IX). Increased expression of NOS has been observed in human colon, ovary, breast, and central nervous system tumors, with iNOS mainly located in the immune cells, endothelium, and tumor cells, indicating a pathophysiological role in tumor-associated NO production. 3-Nitrotyrosine, a marker for peroxynitrite formation, was detected in a population subset of tissue mononuclear cells, and vascular endothelial growth factor (VEGF) was detected in adenomas expressing iNOS, suggesting that NO may be a contributor to colon cancer progression. Additionally, NO was associated with tumor growth, angiogenesis, and metastasis in patients with solid tumors of the head and neck, which positively correlated

with the levels of total NOS, iNOS, cGMP, and microvessel densities. Lymph node metastases contained higher NO levels and microvessel density than lymph nodes without metastatic involvement. Inhibition of NO production reduced tumor growth and angiogenesis, suggesting a key role for NO in tumor metastasis in these patients. The total NOS activity in lung adenocarcinoma specimens was significantly higher than in the normal lung tissue or in other types of lung cancer, suggesting that NO may play a role in the growth, progression, and metastatic spread of certain lung tumors. Exogenous NO or iNOS expression induced in human fibrosarcoma tumor cells by cd15/endothelial-leukocyte adhesion molecule-1 (ELAM-1) adhesion system, enhanced tumor cell adhesion to endothelial cells, increased endothelial permeability, and facilitated tumor cell invasion. Ultraviolet A (UVA)-irradiated human squamous cell carcinoma cells were shown to release NO, peroxynitrite, nitrosocompounds, ammonia, and hydroxylamine. Formation and release of these nitrogen products was time and concentration-dependently stimulated by UVA and inhibited by *N*-methyl-L-arginine (NMA). These cells have a higher NOS and soluble guanylate cyclase activity than normal keratinocytes, and this may be a reason for the poor prognosis of patients with squamous cell carcinoma.

ANTIMETASTATIC ROLE OF NO

Tumor heterogeneity allows a specialized tumor cell subpopulation to survive and metastasize, and it was found that some of these cells are unable to express iNOS. In a melanoma cell line, the cells expressing low levels of iNOS produce slow-growing tumors, the cells that produce higher NO levels undergo autolysis and cause the cytolysis of surround-

Table IX Role of Nitric Oxide in Angiogenesis^a

Antiangiogenic effects	Angiogenic effects
↓ Expression of VEGF, VEGF-R, PDGF	↓ p53 → ↓ thrombospondin-1
↓ Expression of MMP	↑ IL-8 expression
↓ Smooth muscle cell migration	↑ Vascular permeability
↓ DNA synthesis	↑ DNA synthesis
↓ Cell proliferation (endothelium and smooth muscle cells)	↑ bFGF release Stimulates endothelial cell proliferation Inhibits smooth muscle cell proliferation
↓ Capillary density	↑ Cell proliferation
↓ Collagen synthesis	↑ Cell migration
↑ p53 → ↑ thrombospondin-1	↑ Capillary density
	↑ Capillary growth
	↑ Blood flow in solid tumors
	↑ Maintain optimum pH in solid tumors
	↑ Tumor oxygenation

^a↑, increased activity; ↓, decreased activity. Abbreviations: VEGF, vascular endothelium growth factor; VEGF-R, vascular endothelium growth factor receptors; PDGF, platelet-derived growth factor; β-FGF, fibroblast growth factor; IL-8, interleukin-8; MMP, matrix metalloproteinase.

ing cells, whereas the cells unable to express iNOS establish rapid liver metastases. LPS and cytokine treatment results in iNOS induction and high NO level production only in non-metastatic cells. Increased NO production by the tumor cells or by the host immune cells, or transfection of the iNOS gene to the tumor cells or to the host immune cells, leads to tumor suppression. This antimetastatic effect of NO, occurs either by apoptosis, or by alterations in the genes that regulate metastasis (cell survival, invasion, and angiogenesis genes) (Fig. 5).

Activation of macrophages and vascular cells or administration of NO donor agents, inhibited tumor growth and metastasis in mouse lymphomas, B-16 melanoma, or Lewis lung carcinoma. Pretreatment of macrophages with specific iNOS inhibitors reversed the tumoricidal effects of NO. The highly metastatic K-1735 murine melanoma tumor cells seem to be more sensitive to exogenous NO than the cells in the primary tumor, and their ability to metastasize was dramatically reduced by NO. *In vitro* transfection of these cells to express the active iNOS gene resulted in NO-mediated apoptosis, and iNOS inhibitors prevented apoptotic tumor cell death. *In vivo*, the untransfected cells produced rapidly growing tumors in nude mice, whereas the transfected ones did not. Even in immune-deficient mice, the melanoma cells were not metastatic in the presence of an active iNOS gene. Repeated induction of iNOS expression by cytokines was shown to cause regression of liver metastases in a murine sarcoma cell line *in vivo*.

NO can interfere with other steps of the metastatic process such as expression of adhesion molecules, arrest of tumor emboli, and their extravasation, which are hindered by the vasodilator effect of NO and its ability to inhibit platelet aggregation and adhesion to capillary endothelium. The increased fragility of the circulating tumor cells in the presence of NO and their damage in microvasculature is another mode in which NO prevents metastasis.

It is clear that elevated NO is required to produce tumor cell death and the use of a new therapeutic approach, in which multiple systemic administrations of lipopeptide-containing liposomes and IFN- γ , eradicated established liver metastases of reticulum cell sarcoma in mice. Tumor regression correlated with the increased iNOS expression and NO levels.

However, metastatic cells have developed a number of mechanisms that allows them to evade NO-mediated cytotoxicity. Some tumors produce osteopontin, an inhibitor of NO production in the activated host macrophages or endothelial cells. Metastatic cells from a murine colon carcinoma and K-1735 mouse melanoma, exhibit lower NOS activity than the nonmetastatic cells, suggesting a differential pattern of iNOS induction in response to combinations of cytokines [tumor necrosis factor α (TNF- α), interleukin 1 β (IL-1 β), IFN- γ , which are found in circulation], and LPS. There is a direct correlation between NO production and cytotoxicity, and addition of iNOS inhibitors reverses these effects. Thus, the fate of circulating tumor cells is dependent on the presence of iNOS activating factors and the responsiveness of

the tumor cells to the cytotoxic effects of NO. Hypoxia, oxidative, and nitrosative stress existent in the solid tumor microenvironment, are additional modulators of NO production and effects in biological systems.

NITRIC OXIDE AND ANGIOGENESIS

Angiogenesis, can also be regulated by NO, which has been shown to be both an inhibitor and stimulant of angiogenesis (Table IX, Fig. 5). NO selectively inhibits the expression of MMP a collagenase that promotes both angiogenesis and metastasis, but it does not affect the levels of its natural inhibitor, tissue inhibitor of metalloprotease-1 (TIMP-1), a process that is negatively affected by iNOS inhibitors. Additionally, NO inhibits vascular endothelium and smooth muscle cell proliferation and prevents migration of vascular smooth muscle cells, thus inhibiting the early stages of angiogenesis and tumor development. Elevated NO suppresses the expression of angiogenesis genes at the transcriptional level. VEGF, VEGF receptor transcripts, and platelet-derived growth factor (PDGF), which are both constitutively present and hypoxia-induced (remember, tumor microenvironment is hypoxic), were inhibited by NO and addition of iNOS inhibitors reversed these effects.

NO also stimulates angiogenesis, and its effects can be direct or indirect. In solid tumors, low levels of NO maintain optimum blood flow, pH, and increase tumor oxygenation. Additionally, NO enhances vascular permeability, stimulates proliferation, and migration of endothelial cells, therefore directly supporting tumor growth and neovascularization. Activated human monocytes, which produce low levels of NO, also have an angiogenic effect. Indirectly, NO induces the release of basic fibroblast growth factor (bFGF), which is cytotoxic to vascular smooth muscle cells but stimulates the proliferation of endothelial cells. Also, low levels of NO can induce IL-8 gene expression and indirectly have an angiogenic effect. Substance P releases endothelial NO, which acts as an autocrine regulator of angiogenesis.

NITRIC OXIDE AND CELL DEATH

As shown earlier, NO can exert its tumoricidal effects by inducing apoptosis or necrosis, two biological processes characterized by multiple biochemical and morphological changes that are described in Table X and Fig. 7. Endogenous or exogenously administered NO has been shown to mediate cell death in normal, transformed, and neoplastic cells. LPS and cytokine treatment of murine reticulum cell sarcoma and mastocytoma cell lines, or normal L-929 fibroblasts, exhibited increased NO-mediated apoptosis, an effect that was attenuated by iNOS inhibition. NO delivered from activated macrophages cocultured with murine melanoma, and other tumor cell lines, induced apoptosis in the target cells. Prolonged activation was also shown to produce NO-mediated apoptosis in macrophages. DNA fragmentation was present in both tumor cells generating low levels of NO and in the non-NO-producing bystander cells. Higher and prolonged NO production caused necrosis in both tumor and surrounding cells.

Table X Characteristics of Cell Death

Types of cell death	Biochemical changes	Morphological changes
Apoptosis or programmed cell death: Active, regulated process, induced by alterations in physiological conditions. Requires energy, nucleic acid, and protein synthesis and activation.	Caspase activation Protease and endonuclease activation Cleavage of nuclear and cytoskeletal proteins Protein cross-linking (by transglutaminase activation) DNA fragmentation Intranucleosomal DNA cleavage into oligonucleosomes Plasma membrane alterations Expression of cell death markers on cell surface Redistribution of phosphatidylserine, thrombospondin, and glycoprotein in plasma membrane Phagocytic recognition by adjacent cells Selective cell disposal	Cell shrinkage Loss of plasma membrane asymmetry and attachment Cytoplasm condensation Condensation of chromatin to the margins of nuclear membrane Cell surface blebbing Intranucleosomal DNA fragmentation by a specific endonuclease Distinct laddering and banding on gel electrophoresis Cell detachment Cell fragmentation into apoptotic bodies Phagocytic elimination without inflammatory damage to other cells No inflammatory response Loss of single cells
Necrosis: Passive unregulated process triggered by nonphysiological stimuli. Does not require energy, nucleic acid, or protein synthesis.	Plasma membrane and mitochondrial dysfunction Deregulation of ion homeostasis Release of cytoplasmic contents (proteases, nucleases) Uncontrolled DNA degradation Inflammatory reaction in the surrounding cells	Cell and organelle swelling Lysosomal leakage Microvesicle formation Early rupture of plasma membrane Cytoplasm leakage and cell lysis Clumping of chromatin Smearing of DNA on gel electrophoresis Significant inflammatory response Phagocytosis by macrophages Loss of cell groups

Exogenously administered NO donor agents were also capable of producing apoptotic features in a variety of normal and tumor cell lines. Low NO donor agent concentrations produced different degrees of apoptotic changes in the target cells, whereas higher concentrations of NO donor agent induced cellular necrosis. Different types of NO donors with dissimilar NO release kinetics showed distinct apoptosis-inducing effects. The most rapid and potent apoptotic NO donor compound was *S*-nitrosoglutathione (GSNO). As shown earlier in this chapter, the majority of NO-mediated cytotoxic effects are indirectly produced via interaction of NO with ROS. Peroxynitrite, for example, at low concentrations is apoptotic and at high concentrations is necrotic.

The mechanism of NO-mediated apoptosis is still unclear (Fig. 7; Tables IV and XI), but there is evidence suggesting NO involvement in upregulation of genes that regulate cell death or survival (p53, Fas, caspases, and Bcl-2 family). Expression of p53 has been correlated with increased NO levels and apoptosis in a number of cell types, in a time- and dose-dependent manner. For example, murine melanoma cells, rat normal and cancer cells, and human normal and cancer cells show increased wild type of p53 protein accumulation in the nucleus in the presence of elevated NO levels, suggesting that in these cells NO-mediated apoptosis may be the result of NO-induced DNA damage that triggered the p53 expression. Cells with mutated or missing wild-type p53 do not seem to undergo apoptotic changes. Mutations in conserved

codons of p53 are frequently seen in cancers of the brain, liver, breast, and also in the radon- or smoking-induced lung cancers. Another mechanism by which NO induces apoptosis is by reacting with cytochrome *c* oxidase, thus diverting the electrons to oxygen to form O_2^- and H_2O_2 (Table IV, Fig. 7). The increased H_2O_2 causes DNA damage, which upregulates p53 expression and results in apoptotic cell death.

As in other biological processes, NO has a dual effect, and therefore it can induce apoptosis or protect the cells from it (Fig. 7, Table XI). In most normal cells (rat ovary, thymocytes, hepatocytes) apoptosis can be prevented by NO, whereas in other normal cells (neurons, macrophages), and tumor cells (sarcoma, mastocytoma, melanoma) NO induces apoptosis. This is caused either by an increased p53 expression in response to DNA fragmentation, or by activation of protein kinases A and C, which seem to be part of the NO-induced apoptotic signaling pathway. Indeed, increased p53 expression by low concentrations of NO, suggest that NO may induce apoptosis, whereas high NO levels prevent apoptosis by inhibiting p53 expression. One possible explanation is the reaction of RNOS with zinc finger proteins in DNA that can either cause necrotic cell death, or malignant transformation (Fig. 2).

Transfection of Bcl-2, a cell-survival gene, suppressed apoptosis in cells exposed to NO at concentrations that induce apoptosis in nontransfected cells. NO mediated p53 expression, PARP cleavage, and apoptosis were blocked by Bcl-2 overexpression that resulted in malignancy, supposedly

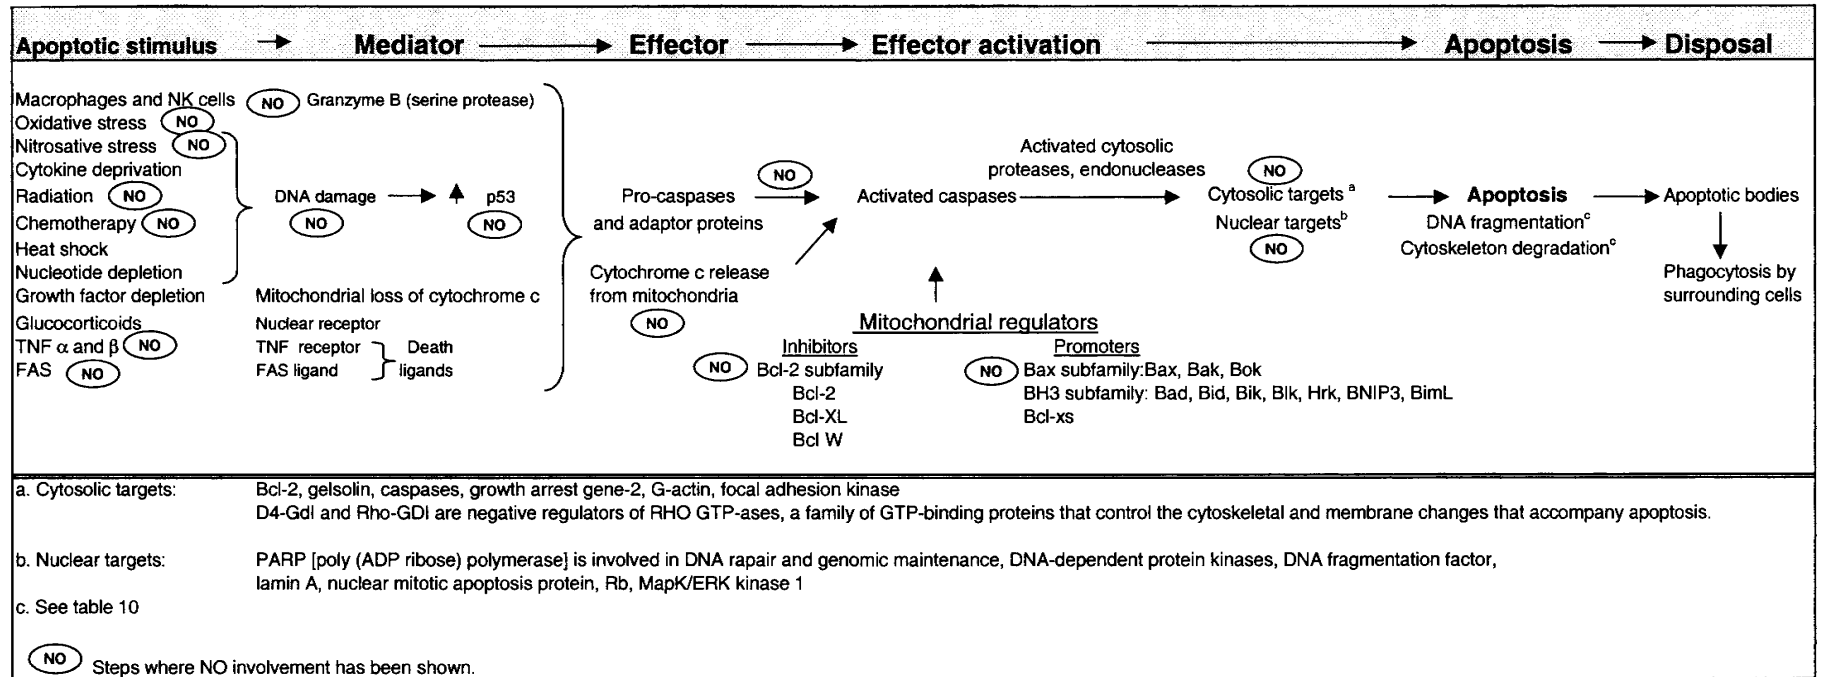

Figure 7 The apoptotic cascade. Schematic illustration of the steps involved in the apoptosis of mammalian cells.

Table XI Effects of NO and RNOS on Apoptosis^a

Proapoptotic effects
↑ Protein kinases A and C
↑ Protein tyrosine nitration → disruption of cell redox status
↑ DNA damage
↑ PARP → PARP cleavage
↑ Intracellular acidification
↑ Intracellular accumulation of calcium and iron ions → cytotoxicity
↑ FAS
↑ p53
↑ Mutagenesis
↓ DNA synthesis
↓ Protein synthesis
↓ ATP levels
↓ Cell energy
↓ Cell respiration
↓ Catalase, cytochrome <i>c</i> oxidase → H ₂ O ₂ cytotoxicity
↓ Glutathione, glutathione peroxidase, metallothionein → cytotoxicity
↓ Bcl-2 (prolonged exposure to high NO levels)
Antiapoptotic effects
↓ Cytochrome <i>c</i> release from mitochondria
↑ Bcl-2 (short, low-level NO exposure)
↓ p53 (prolonged exposure to high NO levels)
↑ Mutagenesis
↑ Carcinogenesis

^a ↑, increased activity; ↓, decreased activity.

due to increased resistance to NO-mediated cytotoxicity. Conversely, downregulation of Bcl-2 lowers tumorigenicity and predisposes the cell to NO-mediated apoptosis. As with other biological systems, in this case too, NO has a dual effect, since it was shown that a short pretreatment of B lymphocytes with low levels of NO could effectively inhibit apoptosis due to sustained Bcl-2 expression. Increased NO levels, however, cause Bcl-2 suppression therefore allowing apoptotic events to take place. Thus, there appears to be a concentration-dependent differential effect elicited by NO on Bcl-2 expression (Table XI).

Additionally, other cellular mechanisms may intervene in NO-mediated cell protection against apoptosis. In a series of cGMP-dependent processes, NO was shown to interrupt the apoptotic cascade in hepatocytes, splenocytes, eosinophils, and lymphocytes, or to inhibit caspase activation and function. Through these mechanisms NO prevents the decrease in Bcl-2 expression and protein, as well as the release of cytochrome *c* from mitochondria. In a cGMP-independent manner, NO prevents apoptosis by interacting with heme-containing proteins such as cyclooxygenases and heme oxygenase-1 or via redox mechanisms that attenuate cell injury. It is possible that NO and O₂⁻ are apoptotic only when they are not in equal steady-state concentrations. At equal steady-state concentrations they produce peroxynitrite, which in the presence of intracellular glutathione may be detoxified to nitrate. All of these examples demonstrate the ability of NO to initiate and/or to arrest cell death. Ultimately, the role of NO in apoptosis is determined by the interaction between the protective and destructive signaling pathways in a given cell milieu.

Environmental Carcinogens

Carcinogenesis is a multistep process that includes initiation, promotion, conversion, cell transformation, progression, invasion, and metastasis. Carcinogenesis involves the action of hereditary and/or environmental factors such as, carcinogenic chemicals, radiation, and oncogenic viruses. Some of the phases of carcinogenesis were discussed earlier, and in this section we will describe only the initiation and promotion steps, as well as their contribution to neoplastic transformation.

Carcinogenic Chemicals

Chemical carcinogens can be produced naturally or artificially (Table XII). Initiation—exposure of cells to the appropriate dose of the carcinogen (initiator), that permanently damages DNA—is followed by exposure to promoters, which can reversibly produce tumors from initiated cells. Alkylating agents and acylating agents, are direct acting initiators that form covalent adducts between the carcinogens and the target cell DNA, RNA, or proteins. The indirect-acting initiators (procarcinogens) require metabolic conversion to become carcinogens. Most of the procarcinogens are metabolized in the liver by the cytochrome P-450 monooxygenases. Detoxification or inactivation of chemical carcinogens is important in evaluation of their biological effects. Because malignant transformation is the result of mutations occurring in oncogenes, antioncogenes, DNA repair, or apoptosis regulating genes, the primary site of action of carcinogens is the DNA. Failure to repair DNA damage is the starting point of initiation, and cell replication renders the mutation permanent (Fig. 2).

Promotion potentiates the carcinogenicity of initiators. Promoters (Table XII) are not mutagenic but are strong inducers of cell proliferation. Forced to proliferate, the initiated clone undergoes additional mutations that ultimately lead to malignancy.

Radiation-Induced Carcinogenesis

Radiation (Table XIII), represented by the UV light and ionizing and particulate radiation, can induce neoplastic transformation in cells. UV light is the main cause of skin cancers. In xeroderma pigmentosum, the inherited inability to repair UV-induced DNA damage results in skin cancer. Ionizing electromagnetic radiation leads to lymphoid malignancies in patients diagnosed with ataxia-telangiectasia. Particulate radiation is responsible for a variety of cancers, which are the consequence of the cumulative effect of radiation exposure over long periods of time.

Viral Carcinogens

A number of DNA and RNA viruses are oncogenic (Table XIV). Some DNA oncogenic viruses are known to cause cancer in animals, whereas others have been implicated in

Table XII Chemical Carcinogens

Chemical carcinogen type	Tumor type
Initiators	
Direct acting (carcinogens)	
Alkylating agents	
Anticancer drugs	Lymphoid neoplasms
Immunosuppressants	Leukemias
Acyating agents	
Indirect acting (procarcinogens)	
Aromatic polycyclic hydrocarbons (cigarette smoke, broiled, smoked meats)	Sarcomas, skin, lung, bladder carcinomas
Drugs	
Heterocyclic hydrocarbons	
Azo dyes (food coloring)	Hepatocellular and bladder carcinoma
Aromatic amines	Hepatocellular and bladder carcinoma
Aromatic amides	
Plant and microbial products (betel nuts, safrole, griseofulvin, aflatoxin)	Hepatocellular carcinoma
Insecticides, fungicides, herbicides	Lymphomas, sarcomas
Metals (chromium, nickel, arsenic)	Lung, liver, skin cancers
Asbestos	Mesothelioma, bronchial, gastrointestinal, prostate, nasal carcinoma
Nitrosamines, amides	Gastrointestinal carcinoma
Promoters	
Hormones (estrogens)	Liver, endometrial, vaginal cancers
Drugs	
Phorbol esters	
Okadaic acid	
Artificial sweeteners	

human cancers. Transforming DNA viruses form stable associations with the genome of the host cell. RNA oncogenic viruses (retroviruses) are known to cause cancers in animals. Only one human retrovirus is presently known, human T-cell leukemia virus type 1 (HTLV-1), which is associated with a form of T-cell leukemia and lymphoma described in certain parts of the world.

Host Defense

Antitumor activity of the host can be cellular and humoral, and it was shown that immunodeficient animals or immunosuppressed transplant and AIDS patients exhibit an increased frequency of lymphomas. Nevertheless, the majority of cancers occur in persons that are not immunodeficient,

Table XIII Radiation-Induced Carcinogenesis

Radiation type	Cellular effects	Tumor type
Radiation		
Ultraviolet (UV) light		
[UVA (320–400 nm), UVB (280–320 nm), UVC (200–280 nm)]	↓ cell division, inactivation of DNA repair enzymes, mutagenicity (ras, p53), cytotoxicity	Squamous cell carcinoma, basal cell carcinoma, malignant melanoma
Ionizing electromagnetic (X rays, Gamma rays)		
Particulate		
(alpha particles, beta particles, protons, neutrons)	DNA lesions, DNA cross-links, DNA–protein cross-links, oxidation, degradation of bases, damage of sugar–phosphate bonds, single- and double-stranded DNA breaks, ↓ DNA repair genes, ↑ free radicals, ↑ oxidative stress, ↑ NF-κB, ↑ gene expression	Skin cancers, cancers of the breast, lung, colon, thyroid, and salivary glands

Table XIV Viral Carcinogens

DNA oncogenic (transforming) viruses	RNA oncogenic viruses (retroviruses)
Animal viruses	Animal retroviruses (slow transforming viruses)
Small DNA polyoma virus	Feline sarcoma virus (FSV)
Adenoviruses	Simian sarcoma virus (SSV)
Bovine papillomavirus	Rodent leukemia virus (RLV)
Simian virus-40 (SV-40)	
Human viruses	Human viruses
Human papillomaviruses (HPV)	Human T-cell leukemia virus type 1 (HTLV-1)
Epstein-Barr herpes virus (EBHV)	Target: T cells, CD4 ⁺ subset
Hepatitis B virus (HBV)	Latency: Long, up to 30 years
Kaposi sarcoma herpes virus (KSHV)	

indicating the presence of immune-evading mechanisms either in the tumor cells or in their environment that allows the host defense mechanisms to fail (Fig. 6). As a result, a number of techniques have been developed, such as immunotherapy and gene therapy to replace or enhance immune activity in cancer patients. Adoptive cellular therapy, for example, is based on the generation of LAK (lymphokine-activated killer) cells from the treatment of peripheral lymphocytes, or tumor-infiltrating lymphocytes with IL-2 in culture, and reinfusion of these cells into patients with advanced metastases. Cytokine therapy activates specific and nonspecific host defense mechanisms and amplifies immune recognition. Furthermore, a number of antibody-based therapeutic methods are used to deliver toxins to tumor cells. Therefore, understanding all the various processes that result in carcinogenesis, is important in identification of molecular targets toward which the use of combined chemotherapy, radiation therapy, immunotherapy, and gene therapy may be effective.

Nitric Oxide and Anticancer Therapy

Radiation Therapy

The toxic effect of radiation to the tumors and normal tissue is the result of ROS and RNOS generation. Hydroxyl radical is the most reactive species *in vivo* that contributes to peroxidation of lipids and nucleic acids following radiation therapy. Reperfusion reoxygenation damage to tumor vasculature between radiation fractions, and the toxicity to normal tissue are probably due to formation of RNOS. The role of NO in radiation therapy was first mentioned in 1957, when it was found to be a radiosensitizer in bacteria. More recently, NO was found to be a hypoxic radiosensitizer in mammalian tumors, possibly by substituting for oxygen in the rapid reactions with carbon-centered radicals formed in DNA by ionizing radiation. The newly formed C-nitroso adducts produce stabilization of radiation-induced DNA damage. Generally the hypoxic milieu of solid tumors restricts the effects of radiation therapy. NO-mediated radiosensitization prevents DNA repair in tumor cells, thereby increasing the effectiveness of this therapeutical approach.

There are a number of changes that occur in normal tissue following irradiation. First there is endothelial damage, which leads to microvascular disruption and altered blood flow. These changes are accompanied by capillary thrombi formation, endothelial swelling, increased vascular permeability, and interstitial edema. Later, aberrant endothelial proliferation and capillary sclerosis completely halts the blood flow and leads to tissue fibrosis. Atherosclerosis may develop in larger vessels due to endothelial dysfunction, erratic proliferation of the cells in the vascular wall, and increased platelet aggregation. The vascular remodeling produced by radiation-induced endothelial damage is noticeably similar to that induced by NO, RNOS, and ROS. Elevated NO causes free radical damage to lipid membranes and DNA. Peroxynitrite diffusion to more distant sites and its decomposition to OH[•] causes additional damage. Lipid peroxidation activates phospholipase A₂ (PLA₂) and increases TNF- α and essential fatty acid consumption. Radiation-induced TNF- α triggers iNOS induction in macrophages and vascular cells, and the increased NO production causes further damage subsequent to each radiation fraction. This type of radiation-induced damage is preventable by thiols, which scavenge free radicals, reduce tissue fibrosis by attenuating the accumulation of macrophages and mast cells, and thereby, reverse endothelial damage.

Tissue undergoing remodeling after radiation injury is populated by mast cells, which release a number of substances such as, histamine, heparin, proteases, hydroxylases, peroxidase, and SOD. Some of these substances impair both the NO production and its effects, thus reducing the cytotoxicity of macrophages and fibroblasts in the irradiated area. During tissue repair, the angiogenic effect of macrophage-derived TNF- α , is reduced in the presence of the mast cells, an effect that also attenuates the NO production. In the absence of mast cells, however, TNF- α induces NO accumulation, which in turn by inhibiting cell proliferation, reduces angiogenesis and tumor growth.

In intermediate stages of radiation-induced damage, the normally quiescent endothelial cells start an abnormal pattern of dedifferentiation and proliferation to repair the damaged vessels that may lead to chronic and occlusive fibrosis. Radiation therapy was shown to cause a redistribution and

partial synchronization of the endothelial cell cycle in both tumor and normal vasculature. This may influence endothelial cell sensitivity to the subsequent radiation doses and affect cellular metabolism. For example, production of angiotensin-converting enzyme (ACE), prostacyclin (PGI₂), and tissue plasminogen activator (tPA) was shown to be altered by radiation and to consequently affect tissue hemodynamics, thrombogenicity, and fibrinolysis. Radiosensitivity is cell-cycle dependent, a process known as age response, and endothelial cells are more radioresistant in S phase and more radiosensitive in G₁ phase. Due to age response, smaller vessels are considerably more radiosensitive than larger ones and because tumor vessels contain more cycling cells, the consensus is that radiation may be more damaging to those vessels. In reality, normal cells are also proliferating during tissue repair or growth, and radiation damages them as well. For example, there is increased capillary permeability of the blood–brain barrier, after irradiation treatment. In addition, there is neuronal damage due to increased levels of glutamate produced during the radiation-induced ischemia. The glutamate activation of NOS through the *N*-methyl-D-aspartate (NMDA) receptors, increases calcium flux into the neurons to cytotoxic levels (Table IV). NO in the presence of O₂^{•−} produces ONOO[−], which may diffuse further and damage the surrounding neurons. Irradiation of the heart causes acute cardiac function depression, by quenching endothelial NO by the radiation-produced O₂^{•−} and peroxy-nitrite formation. Late postirradiation effects include cardiomyopathy and premature coronary stenosis. Irradiation of gastrointestinal (GI) tract results in GI dysfunction, whereas prostate gland irradiation produces impotence. These effects are the result of neuronal damage and nNOS dysfunction in nitrergic nerves innervating these organs. Additionally, there is vascular damage that has as a consequence reduction of constitutively produced NO.

In certain types of cancers elevated NO enhances the radiation-induced damage to the tumor, and as a result a number of NO donor agents have been used to directly increase tumor perfusion during radiation therapy. For example, nitrosothiols are good inhibitors of platelet aggregation at concentrations that do not affect the perfusion pressure. NO complexes with nucleophiles (NONOates) improve the tumor blood flow because they can release NO at acidic pH in the hypoxic tumor microenvironment. The NONOates may also inhibit the tumor cell proliferation as we have shown in human and murine colon carcinoma cell lines. There are a number of other compounds that may indirectly augment NO levels in tumors. For example, ACE inhibitors, stimulate endothelial NO release, and superoxide scavengers increase the availability of NO, while lowering the ONOO[−] and HO• levels. This would improve tissue perfusion and reduce the tissue damage by free radicals. Another indirect mode of elevating tumor NO levels is iNOS induction by TNF-α and IL-2, which will result in increased tumoricidal activity and decreased tumor cell proliferation. However, the cardiotoxic side effects to this approach greatly diminish its therapeutic use.

Tumor progression is prevented in certain cancers by drugs that lower the levels of NO in the tumor. These drugs are either selective NOS isoforms inhibitors, or drugs that limit the availability of certain NOS cofactors. Methotrexate, for example, blocks NO production in tumors by inhibiting the tetrahydrobiopterin synthesis. Steroids may counteract the inflammatory response to radiation by inhibiting PKC activity and consequently the induction of iNOS. Ketoconazole lowers the NO levels by preventing TNF-α induction. The mechanism of nicotinamide effect in cancer treatment is still unclear and there are reports that show a direct vasodilator effect, which is independent of NO release. Also nicotinamide inhibits NOS mRNA induction and downregulates TNF-α. As a result, there is a reduction of radiation-induced edema in the presence of nicotinamide. The tumoricidal effects of 5-fluorouracil (5-FU) are increased following radiation when the NO presence increases blood flow in the tumor and the surrounding tissue.

Thus the presence of NO in irradiated tumors has the ability to modulate the free radical-mediated cell damage in both normal and tumor tissues. At physiological NO levels microvascular perfusion is adequately maintained. Lowering the levels of NO in the presence of cytotoxic drugs causes ischemia and leads to tumor and normal tissue necrosis while greatly diminishing the effectiveness of radiation therapy. Conversely, the consequences of high levels of NO during radiation therapy include enhanced tumor and normal tissue damage, increased vascular permeability, and edema.

Chemotherapy

NO plays an important role in the modulation of blood flow and it may alter the toxic effects of some chemotherapeutic drugs in tumors or in normal tissue. Some chemotherapy drugs such as bleomycin, vinblastine, vincristine, and colchicine damage the vascular endothelium. Bleomycin-induced lung damage is probably due to the iNOS induction in alveolar macrophages. The cytokines TNF-α and IL-2 cause the induction of iNOS in the vascular cells, leading to profound hypotension, one of the major side effects of cytokine treatment. The symptoms that accompany vascular damage in cancer therapy include increased vascular permeability, extravasation of plasma proteins and circulating cells, edema, pain, tissue damage and destruction, disseminated intravascular coagulation, hypotension, shock, cachexia, and death. The occurrence of these symptoms is known as multiple organ failure or multiple organ dysfunction syndrome.

The information provided by such findings was used to design tumor reducing treatments, though in many cases the tumoricidal effects produced by immune cell activation were accompanied by serious side effects. For example the use of IL-2 to treat renal cancers had to be discontinued due to severe hypotension, capillary damage, and increased vascular permeability. NO seemed to be the main cause in the hypotensive effect and the endothelial damage produced during IL-2 treatment. Coadministration of NOS inhibi-

tors, or NO scavengers, greatly ameliorated the side effects of IL-2 treatment without compromising its therapeutic efficacy.

Both primary and metastatic tumors are histologically heterogeneous, containing infiltrates with host lymphocytes, macrophages, neutrophils, fibroblasts, and endothelial cells. iNOS can be activated in either tumor or infiltrated cells or in both. It is important to know that tumor regression does not require all cells in the tumor to produce augmented NO levels. The tumor microenvironment contains numerous cytokines and other factors that can both activate or inhibit the production of NO. Among the cytokines produced by stimulation of various cells, IFNs (α , β , and γ) have the potential to directly or indirectly modulate tumor growth through multiple mechanisms. Directly, the interferons inhibit cell proliferation and stimulate differentiation. Indirectly, they can activate the immune and vascular cells to produce NO. In addition, they are antiangiogenic because of the inhibitory action on the angiogenesis genes. IFNs are thus highly effective antitumor agents, although they damage normal tissue and cause severe side effects that render them useless in anticancer therapy. Unlike IL-2, the tumoricidal action of IFN is due to the elevated NO that resulted from iNOS induction. Consequently, the only therapeutic approach in this case is gene therapy. Transfection of the murine IFN- β gene, for example, completely inhibited tumor progression and metastasis produced in nude mice by the highly metastatic human melanoma, colon carcinoma, and renal cell carcinoma. Additionally, the IFN- β generating tumor cells cause both autolysis and cytolysis of surrounding cells in solid tumors, without any systemic side effects. Therefore, this localized, nonspecific, tumorigenic effect is exclusively due to the high local levels of NO.

The previously described symptoms greatly resemble the ones produced by bacterial and fungal proteases, or by bacterial cell wall components such as the negatively charged endotoxin or LPS in gram-negative bacteria and teichoic acid in gram-positive bacteria. There are a number of cellular events that take place at the inflammation site of bacterial infection and in cancerous tissues, and bradykinin (Bkn) and NO are some of the key players in this scenario. These events are responsible for the fluid accumulation in ascitic and pleural carcinomas, or for the increased vascular permeability in solid tumors. As mentioned earlier, MMPs from tumor cells play an important role in the metastatic process. Elevation of NO, Bkn, kallikrein, and MMP IV (also known as a metastatic factor) enlarges the endothelial gap opening, enhances extravasation of immune and tumor cells as well as that of plasma proteins, and promotes collagen IV degradation in interstitial space. The increased pressure in the interstitial tissue allows the reverse transfer of macromolecules, tumor cells, or bacteria into the bloodstream and their dissemination to distant organs. The angiogenic effect of NO further enhances metastatic spread. Consequently, only a cocktail of iNOS, kinin, and kallikrein inhibitors may potentially eradicate microbial infection, septicemia, or cancer.

Considering that systemic chemotherapy often results in damage to normal tissue, different modalities of drug delivery to the tumors have been tested. For instance, administration of phospholipid liposomes containing macrophage activators successfully eradicated liver metastases in mice, without significant systemic side effects. Likewise, the use of highly phagocytic organ specific cells, or transfection of iNOS or INF- γ genes to tumor cells, or transfection of tumor cells with a retrovirus containing the iNOS gene, resulted in tumor cell destruction with dramatic attenuation of undesired side effects. Therefore, all these examples suggest that high, localized NO delivery or production has the most tumorigenic effect, with the least damage to normal tissue.

Administration of cytotoxic drugs results in extensive tumor cell lysis, a process that releases the “injury mediators” including transition metal ions, discussed earlier, that damage normal tissues in the vicinity of cancer cells. For example, patients receiving chemotherapy for leukemia have been shown to have high levels of free iron in the plasma. Iron ions, in combination with some of the released “injury mediators” such as NO, H_2O_2 , and O_2^- , may be toxic to both tumor and normal tissue, and contribute to the unwanted side effects of chemotherapy. Ideally, agents that selectively modulate individual NOS isozymes, and distinguish the normal tissue from the diseased one, as well as specific free radical scavengers in combination with radiation or chemotoxic drugs may be efficacious and able to improve the therapeutic gain.

Additional research is indispensable to fully understand the multiple roles played by NO in tumor inhibition or tumor progression and to improve the delivery of drugs, vectors, and effector cells to solid tumors. Furthermore, identification of NO-resistant and NO sensitive types of tumors, improvement of tumor suppression methods, characterization of all additional pathways involved in tumorigenesis, and development of selective drug combinations that have a high tumoricidal effect with minimum damage to normal tissues, are areas that require immediate attention.

Vascular Nitric Oxide in Health and Disease

Patrick Vallance

*Centre for Clinical Pharmacology
University College London
London, England*

NITRIC OXIDE HAS EFFECTS ON VASCULAR TONE, CELLULAR ADHESION, GROWTH AND REMODELING, INFLAMMATION, AND PERMEABILITY. STUDIES IN ANIMALS HAVE DEMONSTRATED THAT THESE PROCESSES ARE INVOLVED IN THE NORMAL HOMEOSTASIS OF THE CARDIOVASCULAR SYSTEM AND, IF ABNORMAL, CAN CONTRIBUTE TO DISEASE STATES. THERE IS NOW ABUNDANT EVIDENCE THAT NITRIC OXIDE BIOSYNTHESIS ALSO PLAYS AN IMPORTANT ROLE IN THE REGULATION OF HUMAN VASCULATURE. INHIBITION OF NITRIC OXIDE SYNTHASES INCREASES VASCULAR TONE AND BLOOD PRESSURE IN HUMANS, AND DEFECTS OF BASAL AND AGONIST-STIMULATED RELEASE OF NITRIC OXIDE ARE FOUND IN A VARIETY OF VASCULAR DISEASES OR IN THE PRESENCE OF RISK FACTORS FOR DISEASE. CHANGES IN NITRIC OXIDE-MEDIATED VASCULAR PROTECTION MAY ARISE FROM COMMON GENETIC VARIATION IN NITRIC OXIDE SYNTHASE GENES, ENVIRONMENTAL INFLUENCES ON ENZYME EXPRESSION OR ACTIVITY, OR A COMBINATION OF GENETIC AND ENVIRONMENTAL INTERACTIONS. OVERPRODUCTION OF NITRIC OXIDE WITHIN THE VESSEL WALL ALSO CONTRIBUTES TO DISEASE. THIS CHAPTER CONSIDERS THE ROLES AND EFFECTS OF NITRIC OXIDE IN HUMAN VASCULATURE AND HIGHLIGHTS OPPORTUNITIES FOR THERAPEUTIC INTERVENTION.

Endothelium-Dependent Relaxation in Humans

Endothelial nitric oxide synthase (eNOS) is found in endothelial cells throughout the cardiovascular tree. Human arteries, arterioles, veins, and venules all show nitric oxide-mediated relaxation in response to agonists such as acetylcholine or bradykinin (Calver *et al.*, 1993). Stimuli that increase nitric oxide mediated vasodilation in human blood vessels are shown in Fig. 1. The evidence that nitric oxide is a regulator of vascular tone in humans is provided by studies in which eNOS has been blocked by *N*^G-monomethyl-L-arginine (L-NMMA) and by the direct detection of NO using a porphyrinic microsensor (Vallance *et al.*, 1995).

Arteries

Epicardial coronary arteries relax in response to acetylcholine, bradykinin, substance P, or increased shear stress, and the relaxation is mediated largely by nitric oxide. The brachial artery behaves similarly. Although a major part of the relaxant response to acetylcholine in human conduit arteries is mediated by NO, the overall response to this agonist is complex. Acetylcholine produces direct vasoconstriction through activation of receptors on smooth muscle cells and can alter the output of norepinephrine from sympathetic nerve terminals (Calver *et al.*, 1993). Thus an altered response to acetylcholine is not synonymous with altered NO generation. Coronary arteries seem to have some basal nitric oxide dilator tone, because infusion of L-NMMA reduces

Figure 1 Endothelium generates nitric oxide to relax the underlying smooth muscle. Agonists such as acetylcholine, bradykinin, and substance P can increase nitric oxide production through interaction with receptors on the endothelial cell. The endothelium is also capable of picking up physical signals in the lumen of the vessel such as increased shear stress. Shear stress is probably detected by specialist ion channels in the endothelial cell membrane. Chemical probes, such as acetylcholine, or physical stimuli, such as increased shear stress associated with flow, are used to probe the NO pathway *in vivo*. Alternatively, NO synthesis can be inhibited with L-NMMA.

resting diameter by about 5% (Lefroy *et al.*, 1993). In contrast, there appears to be little basal nitric oxide dilator tone in the brachial or radial arteries of healthy volunteers. Human conduit arteries show prominent dilation in response to increases in flow (shear stress), and this is blocked by L-NMMA (Joannides *et al.*, 1995). The physiological significance of flow-mediated dilation is not known, but it may help to keep shear stress constant (for review, see MacAllister and Vallance, 1996).

Arterioles

Human resistance vessels (small arteries and arterioles) show marked relaxation to acetylcholine, bradykinin, and substance P (Calver *et al.*, 1993). However, unlike the relaxant responses seen in conduit arteries and veins, in the resistance vessels only part of the response to these agonists is blocked by L-NMMA or other inhibitors of NOS. Some of the residual response may be mediated by endothelium-dependent hyperpolarization, but some may even be endothelium-independent. However, resistance vessels show the most obvious basal NO dilator tone. L-NMMA reduces resting blood flow by about 40 to 50% (Vallance *et al.*, 1989a), and this effect has been observed in skeletal muscle, coronary, renal, and cerebral beds in humans. The reduction in flow in response to L-NMMA represents a near doubling of vascular resistance and indicates that basal NO-mediated dilator tone is approximately equal in magnitude and opposite in effect to the constrictor tone provided by the sympathetic nervous system (Fig. 2).

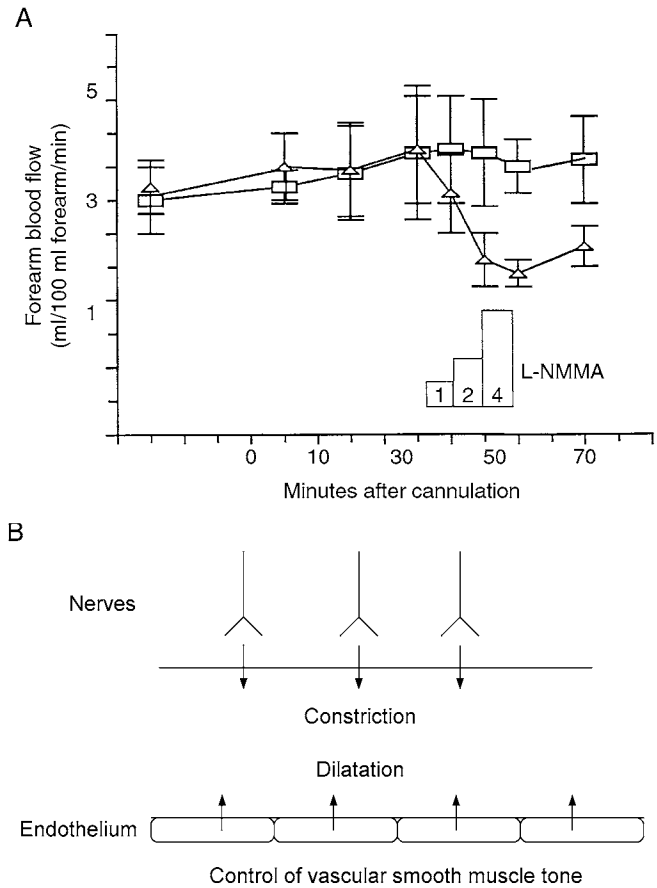

Figure 2 (A) Infusion of L-NMMA into the brachial artery of one arm leads to a dose-dependent fall in resting forearm blood flow. Blood flow in the other arm stays constant. This indicates that there is a basal generation of nitric oxide in resistance vessels, which maintains these vessels in a state of active vasodilation. (B) The NO component of the control of vascular tone seems to be approximately equal in magnitude and opposite in effect to that of the sympathetic nervous system. Together the NO pathway and the sympathetic nervous system provide a local (NO) and a centrally regulated (sympathetic) system for the rapid adjustment of vascular tone.

Veins

Like arteries and arterioles, venous endothelium expresses NOS. However, unlike in the arterial vessels, this NOS appears quiescent under basal conditions (Vallance *et al.*, 1989b). L-NMMA does not seem to cause venoconstriction in humans and does not alter the constrictor responses either to exogenous norepinephrine or to activation of the sympathetic nervous system. However, acetylcholine, bradykinin, and various other agonists produce endothelium-dependent relaxation of human veins, and this can be blocked totally by L-NMMA. Furthermore, the veins are exquisitely sensitive to NO donor agents. Thus the lack of basal NO dilation in veins seems to be due to lack of basal activity of NOS rather than deficient expression of the enzyme or inability of the smooth muscle to respond. The reasons for the arteriovenous difference in basal NOS activity are unclear. It does not relate solely to the environment in which the vessels are studied, since the arteriovenous dis-

tion persists *ex vivo* if the vessels are studied under identical conditions in organ baths. Similar to the responses seen in conduit arteries, in veins the response to acetylcholine is a mixture of endothelium-dependent, NO-mediated relaxation and direct constrictor effects on smooth muscle.

Venules

There have been few studies of human venules. However, the limited data available suggest that venules do not generate NO basally but show pronounced endothelium-dependent relaxation to bradykinin, which is almost entirely due to NO (Riezebos *et al.*, 1994).

Integrated Responses

Systemic inhibition of NOS in humans increases total peripheral resistance and blood pressure (Fig. 3). However the rise in blood pressure is partially offset by a fall in cardiac output (Stamler *et al.*, 1994; Haynes *et al.*, 1993). The mechanism underlying the fall in cardiac output is not known, but it is due to both bradycardia and a fall in stroke volume, and may be a reflex compensatory response. Systemic administration of L-NMMA causes a fall in renal blood flow, and this vascular bed seems to be particularly sensitive to NOS inhibition; indeed, very low doses of NOS inhibitors produce a selective fall in renal blood flow and cause sodium retention. In addition to producing arteriolar vasoconstriction, loss of NO seems to decrease vascular compliance, and this leads to an increase in pulse pressure.

Effects on Circulating Cells

It has been difficult to study the effects of endogenous NO on circulating cells in humans. Studies using human

endothelial cells or vessels *in vitro* clearly show an antiplatelet and antiadhesive action of endothelium-derived NO. However, L-NMMA does not alter platelet aggregation in humans (Vallance *et al.*, 1992a); rather, it produces a small fall in the bleeding time (Simon *et al.*, 1995). This latter effect may be due to effects of platelets but might be secondary to changes in vascular tone. There is also evidence that provision of excess L-arginine might affect monocyte function in humans (Adams *et al.*, 1997), but the mechanisms are unclear.

Assessment of Nitric Oxide in Humans

The L-arginine:NO pathway has been assessed in humans at molecular, biochemical, and functional levels. Each approach has strengths and weaknesses and provides different information on the pathway.

Molecular Studies

In order to probe for the presence of mRNA or to identify NOS protein, it is necessary to remove cells or tissues. For studies of human vasculature this has meant that experiments have had to rely either on cultured cells or on vascular specimens obtained at operation or post mortem. Cellular studies *in vitro* have been of great use, but they may not be directly applicable to the situation *in vivo* or in disease states. The difficulty in obtaining properly matched samples taken in a uniform manner has meant that there have been few studies of the molecular expression or regulation of NOS in intact human blood vessels. Biopsies of human hand veins from healthy volunteers have shown the presence of mRNA for eNOS but not neuronal NOS (nNOS) or inducible NOS (iNOS), and this correlates with the functional responses seen in these vessels (Bhagat and Vallance, 1999).

Biochemical Studies

Biochemical studies of NOS in humans (excepting studies on cultured human cells) have relied on direct enzyme assays in tissue samples, the measurement of products of NOS, or assessment of cyclic GMP levels. Enzyme assays have been useful; however, again, they are dependent on the availability of tissues, and the assays measure the total amount of active enzyme in the sample (measured under near optimal conditions), rather than the level of activity of the enzyme when present in its usual environment *in vivo*. Measurements of products of NOS have included assessment of NO itself, assessment of more stable breakdown products of NO (nitrite or nitrate), measurement of nitrosothiols, or even measurement of citrulline.

Measurement of NO is fraught with problems due to the very short half-life of NO and its rapid destruction on contact with hemoglobin. Although measurement of nitrite and nitrate is more reliable, nitrate is also present in the diet, and so dietary intake may confound interpretation of results

Figure 3 Injection of L-NMMA into healthy volunteers causes a dose-dependent increase in blood pressure. The increase in blood pressure is relatively modest compared to the very large increase in systemic vascular resistance that occurs. The increase in blood pressure is partially offset by a decrease in cardiac output.

(Bayliss and Vallance, 1998). The significance of circulating nitrosothiols is uncertain, and the levels cannot be taken as an index of NO generation. Citrulline is formed by a variety of biochemical pathways, and the plasma concentration of this amino acid is not a marker of NOS activity. Measures of cGMP are useful, but of course this intracellular messenger is also elevated in response to other mediators including atrial natriuretic peptide (ANP).

It is clear therefore that biochemical assessment of NO in humans *in vivo* is far from straightforward. Measurement of plasma nitrite and nitrate probably provides the simplest and most accessible measure, provided diet is controlled. The technique can be improved further by administering [^{15}N]arginine and measuring the generation of [^{15}N]nitrate, since with this approach, at least it is clear that the nitrate derives from the L-arginine:NO pathway (Hibbs *et al.*, 1992; Forte *et al.*, 1997). However, even with a reliable measure of total body NO generation, it is not known how much of the NO comes from the cardiovascular system and how much derives from other cellular sources of NO.

Functional Studies

Nitric oxide is a free radical with a short half-life in biological systems. This has confounded biochemical assessment in humans *in vivo*, but it is also clear that minor changes in the half-life of NO might lead to significant alterations in the amount of active NO reaching target enzymes. Thus while the generation of NO might remain constant, the biological effects of the pathway could vary with minor changes in the stability of the NO generated. An alternative approach to study the L-arginine:NO pathway is to rely on functional assessments of its effects in the cardiovascular system. This has advantages in that it measures the overall consequences of NOS activity, but it should be remembered that this is not necessarily the same as either enzyme activity or amount of NO generated. Nonetheless, most studies of NO in human vasculature have taken a functional approach. Techniques include measurement of blood vessel tone or diameter and assessment of blood flow or blood pressure in a variety of vascular beds. The basal activity of the NO pathway has been studied by blocking NOS with L-NMMA or other inhibitors. The ability of the system to increase NO generation has been studied by measuring responses to agonists (e.g., acetylcholine) or physical stimuli (e.g., shear stress).

Physiology

Endothelial NOS

Basal generation of nitric oxide maintains the arterial circulation in a state of tonic vasodilation. There is evidence that there is increased nitric oxide-mediated vasodilation in response to increased flow or shear stress. The physiological significance of this is discussed in detail elsewhere in this

book. One situation in which this might be important is the response to acute changes in intravascular volume. If a healthy individual is rapidly volume loaded with saline, blood pressure does not change (Calver *et al.*, 1992a). This is because there is arteriolar and venous dilation. At least part of the arterial response is dependent on NO generation, suggesting that in the absence of an effective NO pathway, volume expansion might lead to hypertension.

Certain types of exercise increase NO-mediated dilation in the human forearm (Dyke *et al.*, 1995; Kingwell *et al.*, 1997). There appears to be an acute effect of exercise, and it is possible that this is mediated by increased flow secondary to enhanced cardiac output. Chronic exercise training might also increase endothelium-dependent vasodilation in humans, but the results are conflicting. Studies from animals and cultured cells suggest that such an effect might be mediated by induction of expression of eNOS by chronic increase in shear stress or mediated by alterations in the subcellular localization of eNOS (Garcia-Cardena *et al.*, 1998). Ischemia also causes vasodilation in human skeletal muscle and other beds, but this effect is probably not mediated by NOS activity.

The L-arginine:NO pathway is regulated in part by sex steroids. Estrogens can induce expression of eNOS in a variety of systems (Kausar and Rubanyi, 1997) and increase endothelium-dependent relaxation. There is evidence that flow-mediated dilation of the brachial artery alters throughout the menstrual cycle and that NO-mediated dilation is increased in normal pregnancy (Williams *et al.*, 1997). Pregnancy is associated with vasodilation of resistance vessels, an increase in arteriovenous shunts, and increased circulating blood volume. Studies in pregnant women have shown an increase constrictor response to L-NMMA and a decrease in constrictor response to norepinephrine in the hand circulation during pregnancy (Williams *et al.*, 1997), (Fig. 4). It is likely that this effect is dependent on estrogens, but it is also possible that increased shear stress contributes. Finally, other hormones, including insulin, might also affect endothelial NO, and there is evidence that insulin causes NO-dependent vasodilation in the human forearm (Steinberg *et al.*, 1994).

Neuronal NOS?

The role of nNOS in regulating vascular tone in humans is not clear (except in the genital tract; see elsewhere in this volume) (Fig. 5). In the cerebral circulation NO generated from nNOS is thought to be important in the process of vasoneuronal coupling, the mechanism by which neuronal activation leads to an appropriate increase in blood flow to the active brain region. However, studies with L-NMMA in healthy volunteers have failed to detect a significant effect of NO on vasoneuronal coupling. These studies do not rule out an effect of nNOS in the brain, however, since L-NMMA may not cross the blood-brain barrier sufficiently to inhibit the enzyme. In contrast to results of studies in animals, in humans NO seems to play a relatively minor role in the

Figure 4 L-NMMA produces a greater fall in blood pressure in pregnancy than it does in the nonpregnant state. Studies were undertaken in 10 nonpregnant women (NP), 10 women in early pregnancy (EP), and 10 women in late pregnancy (LP). Vasoconstrictor responses to L-NMMA and to norepinephrine were compared in the forearm arterial circulation. In the nonpregnant state the doses of norepinephrine selected produced a greater fall in forearm blood flow than the doses of L-NMMA used. In early pregnancy the norepinephrine and L-NMMA were approximately equally effective; in late pregnancy the L-NMMA was more effective than the norepinephrine. (From Williams *et al.*, 1997.)

cerebrovascular dilator response to carbon dioxide (White *et al.*, 1998).

In the periphery, local warming causes vasodilation in humans, and in the hand circulation, this appears to be NO-mediated, at least in part (Williams *et al.*, 1995). It is not known whether the effect is mediated by eNOS or is secondary to local neurogenic stimulation and activation of nNOS. Mental stress causes a large increase in blood flow in the human forearm, and it had been assumed that this is due to withdrawal of sympathetic tone. However, it has been shown that L-NMMA blunts the response, but again it is not clear whether the NO originates from endothelium or nerves (Dietz *et al.*, 1994, 1997).

Pathophysiology

Increases and decreases in NO-mediated dilation have been implicated in vascular disease in humans.

Decreased NO-Mediated Dilation

Impaired responses to “endothelium-dependent” agonists, decreased flow-mediated dilation, or decreased constrictor responses to L-NMMA have been detected in patients with essential hypertension, diabetes (type I or type II), or hypercholesterolemia, in active or passive smokers, and in individuals with elevated circulating levels of homocysteine.

HYPERCHOLESTEROLEMIA

The most consistent results have been obtained in patients with hypercholesterolemia, in whom there seems little doubt that there is impairment of endothelium-dependent dilation (for review, see Maxwell *et al.*, 1998). Interestingly, the basal NO-mediated dilation seems to be preserved, but the dilator response to “endothelium-dependent” agonists or flow is impaired. The defect has been seen in conduit arteries (including the coronary vessels) and in resistant beds. Normally, epicardial coronary arteries dilate to low-dose acetylcholine, whereas in patients with raised cholesterol levels, the vessels constrict. A similar pattern of responses is seen in patients with overt atheromatous disease. The functional significance of these changes is not yet known, but impaired endothelium-dependent relaxation would be expected to render the vessels more susceptible to vasospasm or vasoconstriction in response to activated platelets, and might be associated with enhanced platelet and white cell adhesion. Together these changes may predispose to acute vaso-occlusive events, and studies in animals suggest that, if chronic, such changes may enhance atherogenesis. The potential significance of the changes in endothelium-dependent dilation in the resistance vessels is less well understood, but altered endothelial function might lead to dysregulation of the distribution of blood flow within a vascular bed, which

Figure 5 There are three potential enzymatic sources of nitric oxide within the blood vessel wall. eNOS in the endothelium probably accounts for the majority of physiological regulation of peripheral vascular tone. In some vessels, nerves in the adventitia may also release nitric oxide generated by the activity of nNOS. This is probably important in the brain and also in the process of penile erection. In conditions of gross inflammation nitric oxide might be produced throughout the blood vessel wall through *de novo* expression of inducible isoform of nitric oxide synthase.

might cause regional ischemia. Interestingly, the defect seen in patients with hypercholesterolemia is reversed by exogenous L-arginine and possibly by the NOS cofactor tetrahydrobiopterin. This is discussed in greater detail later.

HYPERTENSION

Initial studies in patients with hypertension suggested that responses to endothelium-dependent dilators is diminished in the forearm arterial bed (Panza *et al.*, 1990; Linder *et al.*, 1990). Subsequently it was shown that the constriction to L-NMMA is also decreased in hypertensive subjects and that the higher the pressure, the smaller the response to NOS inhibition (Calver *et al.*, 1992b). Together these studies indicated a defect of both basal and stimulated NO-mediated dilation in hypertension. However, results have not been uniformly consistent (Cockcroft *et al.*, 1994). Some studies have failed to detect differences in responses to endothelium-dependent agonists or L-NMMA between hypertensive and normotensive subjects. Furthermore, it has been reported that flow-mediated dilation was preserved to normal levels in hypertensives. More recently, studies with [¹⁵N]arginine have demonstrated that hypertension is associated with significantly reduced rates of production of NO (Forte *et al.*, 1997). In addition, a retrospective analysis of many hundreds of individuals who have taken part in studies of flow-mediated dilation of the brachial artery has identified the level of blood pressure as the major determinant of the response. Thus, although there are some discrepancies within the literature, the bulk of the available evidence supports the notion that there is a functional defect in NO-mediated dilation in many individuals with raised blood pressure, that there is an inverse relationship between the level of blood pressure and NO-mediated dilation, and that the defect is likely to be due to a true deficit in NO generation.

Data on the reversibility of the endothelial dysfunction in hypertension are also somewhat contradictory. However, several studies have shown that lowering blood pressure restores the response to L-NMMA toward normal (Calver *et al.*, 1994; Lyons *et al.*, 1994), suggesting that the defect is a consequence of the raised pressure rather than a primary cause. There is no convincing evidence that any one class of antihypertensive agents is any more or less likely than any other to restore endothelial function. Patients with secondary hypertension also seem to have impaired endothelium-dependent responses, and one study has suggested a genetic component to the defect, because unaffected normotensive offspring also seemed to have an impairment of normal endothelial function (Taddei *et al.*, 1996).

DIABETES

Patients with type II diabetes have impaired endothelium-dependent dilation to agonists and to flow. The situation with type I diabetes is less clear-cut, but it seems as though responses to L-NMMA are decreased (Calver *et al.*, 1992c; Elliott *et al.*, 1993) and might be most markedly abnormal in those individuals who have evidence of proteinuria. Unlike the situation in hypertension, in diabetes there is increas-

ing evidence to suggest that the generation of NO might be normal, and that the defect might be due either to increased destruction of NO or to decreased sensitivity of the smooth muscle effector systems to NO. One possibility is that increased generation of oxygen free radicals leads to more rapid degradation of the NO. Several studies have also suggested that insulin resistance is associated with endothelial dysfunction; indeed, it has been hypothesized that endothelial dysfunction might be the primary cause of insulin resistance and contribute to both metabolic and vascular effects of the syndrome (for review, see Cleland *et al.*, 1998).

MECHANISMS OF CHANGES

The mechanisms of alterations of NO-mediated dilation are likely to vary between disease states and between individuals. The gene for eNOS shows polymorphic variation (Fig. 6), and several of these variants have been associated with altered cardiovascular risk. However, it is not yet known how or whether the variants alter expression or activity of eNOS in humans *in vivo*.

In diabetes, increased generation of oxygen radicals ("oxidative stress") seems to be a likely mechanism of impaired endothelium-dependent dilation, and this might also be important in individuals with overt atheroma. Although acute systemic inflammation can be associated with increased NO generation and vasodilation (see later), there is also evidence that some types of inflammatory responses may lead to impaired endothelium-dependent relaxation. The cytokine tumor necrosis factor α can induce profound endothelial dysfunction in humans (Bhagat and Vallance, 1997), and this might also be mediated by increased generation of oxygen free radicals that decrease the bioavailability of NO.

In hypercholesterolemia there is some evidence to suggest that a defect in tetrahydrobiopterin can contribute to the impairment of endothelium-dependent relaxation. There is also strong evidence to suggest that L-arginine can restore normal endothelial function. This is an unexpected observation since the K_m for arginine as a substrate for NOS is of the

Figure 6 Several common variants of the eNOS gene occur in the population (polymorphic variations). Some of these are nonfunctional, some occur in the promoter region, and one encodes an amino acid substitution (Glu for Asp at position 298). In the United Kingdom about 10% of individuals are homozygous for the Glu variant, and about 50% are homozygous for the Asp variant. The Glu variant has been suggested to be associated with increased risk of coronary artery disease and other vascular problems. Association between other polymorphic variations and cardiovascular diseases have also been reported.

order of 1–2 μM , the circulating concentration of arginine is of the order of 50–100 μM , and the intracellular concentration of this amino acid may reach 1 mM. Thus arginine should not be rate limiting for NOS under normal circumstances. Indeed, this is the case in healthy individuals, in whom provision of excess arginine does not increase NO production through the mechanism of provision of excess substrate. The changes that occur in the presence of hypercholesterolemia that result in arginine apparently becoming rate limiting for stimulated NO-mediated dilation are not known. One possibility is that, owing to subcellular compartmentalization of NOS, there is a true local deficit in arginine in this condition. Another possibility is that accumulation of endogenous methylarginines, which inhibit NOS, alters the apparent K_m for arginine (Fig. 7). Endogenous methylarginines are found in increasing concentrations in individuals with hypercholesterolemia (Leiper and Vallance, 1999), and the plasma levels seem to correlate with endothelial dysfunction and with intimal thickening in the carotid artery. Such compounds also accumulate in patients with renal disease, another situation in which endothelial function seems to be impaired, and the defect is reversed by L-arginine (Vallance *et al.*, 1992b).

CONSEQUENCES OF CHANGES

Decreased functional activity of the L-arginine:NO pathway, whether this is due to decreased NO generation, increased destruction of NO, or decreased sensitivity of targets for NO, would be expected to alter vascular reactivity as well as platelet and white cell function. Ultimately, the changes may promote atherogenesis and/or enhance the likelihood of vessel occlusion. Interestingly, not all conditions associated with apparent loss of NO-mediated dilation cause hyper-

tension, yet loss of NO would be expected to raise blood pressure. However, the major effect of NO is on vascular resistance rather than blood pressure, and it is clear that significant changes in resistance can occur before blood pressure is affected. Furthermore, hypertension is more prevalent in patients with other conditions associated with endothelial dysfunction, and indeed patients with diabetes or hypercholesterolemia tend to have higher blood pressures than age- and sex-matched healthy control subjects. The other important consequence of loss of NO-mediated dilation might be to decrease vascular compliance. This would have profound long-term hemodynamic consequences and would cause a “stiffer” vasculature.

Increased NO-Mediated Dilation

Increased NO production would be expected to cause vasodilation and might also disrupt normal regulation of vascular tone. There is abundant evidence from studies in animals and *in vitro* that certain inflammatory stimuli cause vasodilation by stimulating increased NO generation (for review, see Vallance and Charles, 1998). There is increasing evidence that the same occurs in humans *in vivo*, although mechanisms underlying the increased NO generation may differ between rodents and humans.

SEPTIC SHOCK AND SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

Most patients with overwhelming acute systemic infection have hypotension, and the fall in blood pressure is due largely to a fall in systemic vascular resistance. At local levels this vasodilation might also impair appropriate distribution of oxygenated blood within tissues. There is biochemical evidence for increased generation of NO in patients with septic shock, in whom plasma concentrations of nitrite and nitrate are of the order of 50–100% higher than those seen in healthy control subjects (Evans *et al.*, 1993). Patients treated with the cytokine IL-2 also develop a septic shock-type systemic vasodilator response, and this is associated with a rise in the circulating concentrations of nitrate. Furthermore, in this situation, studies with [^{15}N]arginine have been undertaken, and it has been clearly shown that the nitrate derives from arginine (Hibbs *et al.*, 1992). The vasodilation and hypotension in septic shock or IL-2 induced shock are both reversed by L-NMMA, indicating that increased NO-mediated dilation contributes to the cardiovascular collapse. Administration of L-NMMA to patients with septic shock leads to arterial vasoconstriction in systemic and pulmonary beds and also causes venoconstriction, indicating that in this situation the veins also begin to generate significant amounts of “basal” NO (Petros *et al.*, 1991, 1994). It remains to be determined whether the overproduction of NO that occurs also contributes to impaired tissue oxygen consumption through effects on mitochondrial enzymes.

In rodents the mechanism of the increased vascular NO generation in response to bacterial endotoxin or certain proinflammatory cytokines is well established. The inflam-

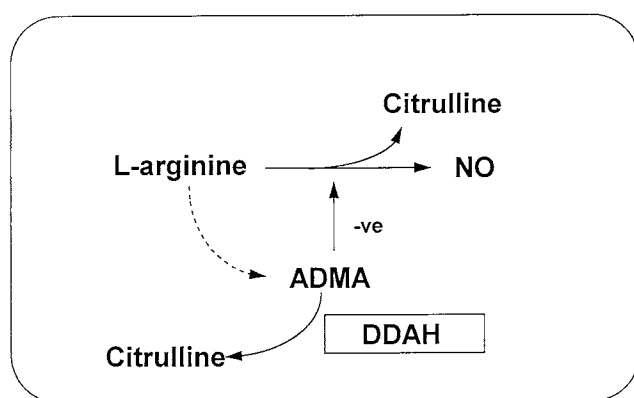

Figure 7 L-Arginine is converted to nitric oxide by the action of nitric oxide synthase. However, it can also be methylated in the guanidino nitrogens to produce L-NMMA and dimethylarginines. One of the dimethylarginines, asymmetric dimethylarginine (ADMA), is an inhibitor of NOS. This compound circulates in the plasma, is excreted in the urine, and is concentrated within cells. Certain cells also express the enzyme dimethylarginine–dimethylaminohydrolase (DDAH), which metabolizes ADMA back to citrulline, thereby inactivating the inhibitor. There is increasing interest in the possibility that endogenous ADMA might regulate the amount of NO synthesized in health or disease. -ve, inhibition of NOS activity.

matory mediators induce expression of iNOS in vascular smooth muscle, and this results in the generation of large amounts of NO. It is not yet clear whether the same mechanism occurs in humans (Fig. 8). Certainly human vascular cells can be induced to express iNOS, but they do so less readily than do rodent cells. In a model in humans in which human superficial veins were incubated *in situ* with pro-inflammatory cytokines, NO generation was induced, and this was sufficient to blunt the constrictor response to nor-epinephrine and abolish sympathetic-induced venoconstriction (Bhagat and Vallance, 1999). In this model, however, no iNOS was detected, and the NO seemed to be derived from eNOS. The cytokines did induce expression of GTP cyclohydrolase-1, expression of which is rate limiting for the generation of tetrahydrobiopterin, and it is possible that overproduction of this cofactor for NOS is important in the genesis of the response. It has been known for many years that pterin synthesis is increased during infection or inflammatory states, and it is possible that induction of GTP cyclohydrolase-1 is an important component of the overall increase in vascular NO generation seen in a wide range of inflammatory states (Bhagat and Vallance, 1999).

ACUTE LOCAL INFLAMMATION

The role of NO in mediating the vasodilation that characterizes acute localized inflammatory responses in humans has not yet been established. However, endothelium-derived NO mediates part of the dilator response to histamine and bradykinin, two mediators that are important in the vasodilator response of acute inflammation.

Therapeutic Implications

Strategies for boosting endogenous NO may be useful for preventing vascular complications of hypertension, diabetes, or hypercholesterolemia. On the other hand, decreasing ab-

normally high production of NO might have benefit for the treatment of conditions associated with excessive inflammatory vasodilation.

Boosting NO-Mediated Dilation

NO donor agents have been in clinical use for over 100 years and form the mainstay of treatment for patients with angina. Newer drugs that liberate NO differentially in different tissues may offer theoretical advantages over the older drugs, and one class of compounds, the nitrosothiols, appear to show significant antiplatelet effects in humans at doses that do not cause much vasodilation (de Belder *et al.*, 1994). This is unlike the classic NO donor agents that show prominent vasodilator actions (mainly venodilator) and little antiplatelet effect. It remains to be determined whether these or other properties of novel NO donor agents translate into clinical benefit.

Supplementation with L-arginine improves certain aspects of NO-mediated dilation in patients with hypercholesterolemia. The precise mechanism (i.e., one which explains why arginine should be rate limiting for NO generation) is unclear; however, numerous studies have now confirmed the initial observation, and clinical trials even suggest that arginine supplementation may improve hard clinical end points, such as walking distance, in patients with peripheral atherosclerosis. It will now be important to undertake properly powered clinical studies to determine the magnitude and clinical usefulness of effects of arginine supplementation in this and other conditions. If it does prove to be effective, arginine supplementation would appear to offer an inexpensive and freely available therapeutic option. Studies with tetrahydrobiopterin also seem to show some improvement of endothelium-dependent relaxation in certain patient groups, but the tetrahydrobiopterin has to be given intravenously. However, therapeutic strategies aimed at boosting levels of this cofactor might be useful.

Figure 8 Certain proinflammatory cytokines such as interleukin-1 β (IL-1 β) and γ -interferon (IFN- γ) may increase NO generation either by inducing expression of iNOS or by inducing expression of GTP cyclohydrolase 1 (GTPCH-1). Induction of GTPCH-1 leads to generation of tetrahydrobiopterin (BH₄), an essential cofactor for all isoforms of NOS. Induction of GTPCH-1 may enhance NO output from eNOS, or from iNOS if this isoform is expressed. Studies in human endothelial cells and human veins *in vivo* suggest that induction of GTPCH-1 and subsequent activation of eNOS may be an important mechanism in human vessels.

In addition to using NO donor agents or providing excess arginine, several other therapeutic possibilities have emerged. These include gene transfer of eNOS, agents to stimulate guanylate cyclase, and agents that decrease superoxide production or increase its destruction. There are now well-established models in humans in which such therapeutic approaches could be tested.

Blocking NO-Mediated Dilation

It is still unclear whether blocking overproduction of NO will produce beneficial effects in conditions of inflammatory vasodilation. Studies in animals have been contradictory, but it does appear as though complete or near complete inhibition of NOS is likely to be harmful. Studies in animals have indicated that in some situations selective inhibition of iNOS may offer therapeutic advantages over nonselective inhibitors such as L-NMMA that inhibit all three isoforms of NOS. However, even with selective inhibitors it seems as though it will be important to aim for a modest degree of inhibition only. Ultimately, the test of inhibitors will come in clinical trials, in which hard clinical end points can be assessed.

Clinical Therapy with Inhaled Nitric Oxide in Respiratory Diseases

William E. Hurford, Wolfgang Steudel, and Warren M. Zapol

*Department of Anesthesia and Critical Care
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts*

MANY INSIGHTS INTO THE MECHANISMS OF ACTION OF NITRIC OXIDE (NO) HAVE BEEN RAPIDLY APPLIED TO TREAT PATIENTS. SINCE THE REPORTED APPLICATIONS OF INHALED NO IN THE LABORATORY (FROSTELL *et al.*, 1991) AND IN ADULT PATIENTS WITH PRIMARY PULMONARY HYPERTENSION (PEPKE-ZABA *et al.*, 1991), HUNDREDS OF STUDIES HAVE BEEN CONDUCTED TO DETERMINE THE CLINICAL APPLICABILITY OF INHALED NO. IN SELECTED GROUPS OF SEVERELY ILL AND HYPOXIC CHILDREN AND ADULTS, INHALED NO IMPROVES ARTERIAL OXYGENATION AND SELECTIVELY REDUCES PULMONARY ARTERIAL HYPERTENSION (PAH). NO INHALATION THERAPY, IN COMBINATION WITH CONVENTIONAL (NEONATAL INHALED NITRIC OXIDE STUDY GROUP, 1997A; ROBERTS *et al.*, 1997) OR HIGH-FREQUENCY OSCILLATORY VENTILATION (KINSELLA *et al.*, 1997), CAN SIGNIFICANTLY IMPROVE ARTERIAL OXYGENATION AND REDUCE THE NEED FOR EXTRACORPOREAL MEMBRANE OXYGENATION (ECMO), AN EXPENSIVE AND INVASIVE SUPPORT PROCEDURE IN NEWBORN PATIENTS WITH HYPOXIC RESPIRATORY FAILURE. HOWEVER, IT REMAINS UNCERTAIN WHETHER NO INHALATION IMPROVES SURVIVAL RATES IN ADULTS WITH SEVERE ACUTE LUNG INJURY.

NEW APPLICATIONS FOR NO INHALATION HAVE BEEN DISCOVERED. STUDIES INDICATE THAT INHALED NO MAY DECREASE ISCHEMIA–REPERFUSION INJURY (BACHA *et al.*, 1996) AND MAY BE USEFUL TO TREAT THROMBOTIC DISORDERS (ADRIE *et al.*, 1996; NONG *et al.*, 1997). BY INCREASING THE O₂ AFFINITY OF SICKLE CELL HEMOGLOBIN, INHALED NO MAY PREVENT OR TREAT SICKLE CELL CRISIS. THIS CHAPTER WILL REVIEW THESE DIVERSE CLINICAL APPLICATIONS FOR INHALED NO THERAPY.

Background

Nitric oxide (NO) is a small, easily diffusible molecule that can be administered simply by inhalation. Because avid binding of NO to hemoglobin limits the action of NO in the systemic circulation, inhaled NO produces selective pulmonary vasodilation, a long-sought action that should be useful in the treatment of many lung diseases. Many studies have concluded convincingly that inhaled NO is a selective pul-

monary vasodilator, in a variety of both animal models and clinical conditions.

The administration of inhaled NO often improves systemic oxygenation during acute lung injury. Commonly used intravenously administered vasodilators diffusely release hypoxic pulmonary vasoconstriction within the lungs and can worsen oxygenation. Inhaled nitric oxide, by being delivered to areas of the lungs that are best ventilated and then by being rapidly bound to hemoglobin and inactivated in

the circulation, can selectively vasodilate ventilated lung regions. Regions of the lungs that are not ventilated are not exposed to inhaled NO. Oxygenation improves via a reduction in relative blood flow to nonventilated regions.

Borland and co-workers administered inhaled NO to patients and volunteers to determine the diffusing capacity of the lung (Borland and Higenbottam, 1989). They found that a single breath of nitric oxide could be administered safely. Because NO is also an atmospheric pollutant (Alberts, 1994), human toxicity studies (von Nieding *et al.*, 1975) and exposure recommendations (Centers for Disease Control, 1988) had been previously reported and provided the foundation for initial clinical studies. Today, substantiated indications for inhaled nitric oxide (Table I) include hypoxic respiratory failure of the newborn (Clark, 1999; Hoffman *et al.*, 1997; Kinsella *et al.*, 1997; Neonatal Inhaled Nitric Oxide Study Group, 1997a; Roberts *et al.*, 1997) and the assessment of pulmonary vascular reactivity in patients with pulmonary hypertension (Fishman *et al.*, 1998). Inhaled NO has also been used in the treatment of acute respiratory distress syndrome (ARDS), lung and cardiac transplants, congenital and acquired heart disease, and chronic pulmonary hypertension, and it has been used to produce desirable direct effects on blood elements, specifically for the treatment of acute chest syndrome in sickle cell disease.

Neonatal Respiratory Failure

Persistent pulmonary hypertension of the newborn (PPHN) is a clinical syndrome characterized by sustained pulmonary hypertension and severe hypoxemia, resulting in cyanosis that is unresponsive to oxygen therapy. Persistent pulmonary hypertension of the newborn may be due to a variety of etiologies (Roberts, 1993). Diagnostic confirmation of PPHN includes echocardiographic observation of a right-to-left shunt through the ductus arteriosus or foramen ovale, due to increased pulmonary vascular resistance (PVR), in the absence of congenital heart disease. Conventional treatment strategies include breathing high inspired O₂ concen-

trations (FiO₂), mechanical ventilation with high-frequency oscillatory ventilation, hyperventilation and infusion of bicarbonate to produce alkalosis, inhalation treatments with bovine surfactant, and intravenous vasodilator therapy. Where available, extracorporeal membrane oxygenation is used to treat severe hypoxemia. The anticoagulation and cannulation of large vessels required for ECMO, however, is associated with hemorrhagic complications. In adults receiving ECMO, bleeding complications have been reported to occur in 88% of patients (Anderson *et al.*, 1993). Bleeding at a rate of over 1.3 liters per day is common (Pesenti *et al.*, 1988). In neonates, intracranial hemorrhage occurs at a rate of approximately 15% of patients receiving ECMO [ECMO registry of the Extracorporeal Life Support Organization (ELSO), 1996].

In 1992, Roberts *et al.* and Kinsella *et al.* reported that 80 parts per million (ppm) (Roberts *et al.*, 1992) or 6–20 ppm (Kinsella *et al.*, 1992) inhaled NO improved oxygenation in newborns with hypoxic respiratory failure and PPHN. Several controlled, randomized multicenter trials of the effects of inhaled NO in near-term and term hypoxic newborn patients were reported in 1997 (Fig. 1) (Hoffman *et al.*, 1997; Kinsella *et al.*, 1997; Neonatal Inhaled Nitric Oxide Study Group, 1997a,b; Roberts *et al.*, 1997). In the majority of patients with PPHN and hypoxic respiratory failure, NO improved oxygenation and decreased the requirement for ECMO. The decisions to initiate ECMO were made by the clinical team on the basis of center-specific ECMO entry criteria and without knowledge of assignment of the patient to the treatment group or placebo.

It is worthwhile to review several important studies. The Neonatal Inhaled Nitric Oxide Study (NINOS) group of investigators studied 230 infants of at least 34 weeks gestational age with hypoxemic respiratory failure of various etiologies (Neonatal Inhaled Nitric Oxide Study Group, 1997a). They were randomized to receive 100% oxygen or oxygen plus inhaled NO. The use of ECMO was reduced significantly from 54% in the control group to 39% in the NO group. The study did not find a change in mortality that was statistically significant. Roberts and co-workers (1997) randomized 58 infants with severe hypoxemia and PPHN to receive nitrogen or 80 ppm NO.

Oxygenation doubled in 53% of the children receiving inhaled NO versus 7% of controls. This initial effect was sustained in 75% of infants with initial improvement and resulted in a significant reduction in ECMO use from 71% in control patients to 40% in newborns receiving inhaled NO. Kinsella *et al.* (1997) reported that NO inhalation and high-frequency oscillatory ventilation were an effective combination that may increase the rate of responsiveness to inhaled NO. As opposed to studies in adults, in which the ventilatory strategies called for a reduction in lung recruitment (see later), the use of high frequency oscillation in combination with inhaled NO is important for maintaining alveoli open and possibly reducing barotrauma. In follow-up studies of children who received inhaled NO treatment for PPHN, neurodevelopmental scores and growth rates, as well

Table I Clinical Indications for Inhaled Nitric Oxide

Bronchodilation

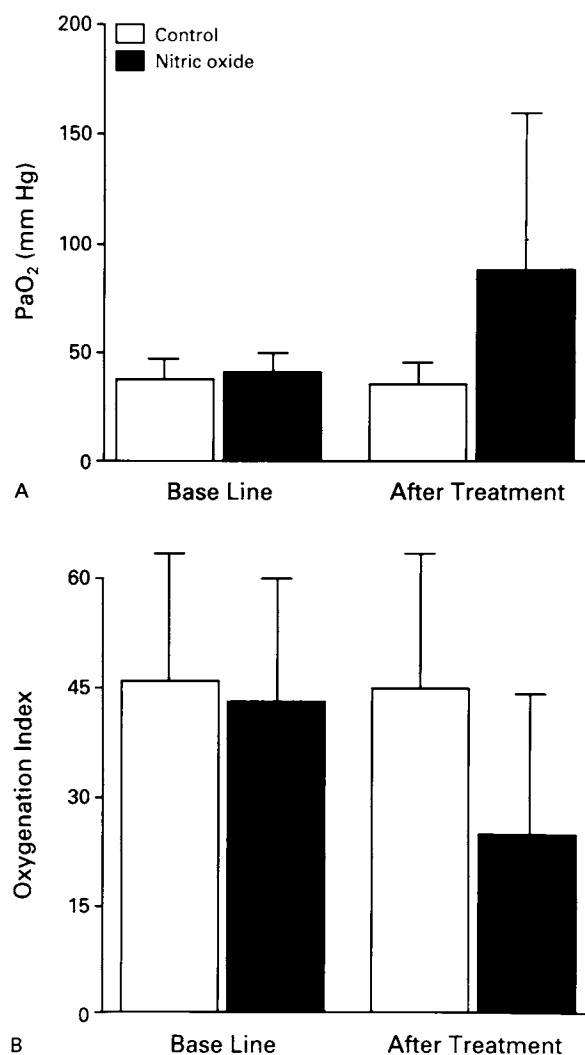

Figure 1 Short-term effects of inhaled NO on systemic oxygenation in infants with severe hypoxemia and persistent pulmonary hypertension of the newborn. Treatment with nitric oxide inhalation (80 ppm at FiO_2 0.9 for 20 min, $n = 30$), but not with placebo inhalation (control, nitrogen at FiO_2 0.9, $n = 28$), after randomized assignment significantly ($p < 0.001$) improved postductal PaO_2 (A) and oxygenation index (B) compared with baseline. Values are means \pm SD. Reprinted with permission from Roberts *et al.* (1997).

as the frequency of airway disease and need for supplemental O_2 , were comparable to conventionally ventilated or ECMO-treated patients (Rosenberg *et al.*, 1997). In summary, inhaled NO improves oxygenation in many newborns and significantly reduces the need for ECMO (Neonatal Inhaled Nitric Oxide Study Group, 1997a; Roberts *et al.*, 1997). These findings have more recently been confirmed in a third multicenter randomized trial (Clark *et al.*, 2000).

The use of inhaled NO to treat PPHN deserves special emphasis. Persistent pulmonary hypertension of the newborn is a relatively uniform disease characterized by severe pulmonary vasoconstriction. By relieving pulmonary vasoconstriction, inhaled NO directly treats one of the major pathological derangements of the disease. Consequently, the

efficacy of NO in PPHN has been substantiated in multicenter, randomized, placebo-controlled trials.

Inhaled NO reduces the necessity for ECMO in newborns with PPHN and infants with hypoxic respiratory failure of various etiologies. This improvement in management will justify its continued use, because of the increased expense of ECMO and its morbidity secondary to its invasive nature and the necessity for systemic anticoagulation. Nevertheless, ECMO remains a necessary lifesaving therapy because inhaled NO is not effective in all patients. Such patients should be treated in a facility providing the possibility of ECMO therapy.

Respiratory distress syndrome (RDS), or hyaline membrane disease of the premature newborn, is characterized by a deficiency or dysfunction of surfactant and is often associated with acute PAH (Kinsella *et al.*, 1994). After promising preliminary studies of inhaled NO in the premature newborn with RDS (Abman *et al.*, 1993; Peliowski *et al.*, 1995), Skimming and associates (1997) studied the effect of inhaled NO at 5 and 20 ppm in preterm neonates (without systemic hypotension or congenital malformations and mechanically ventilated at $\text{FiO}_2 > 0.5$). They demonstrated that arterial oxygenation improved and that systemic arterial blood pressure was unaffected during a 15-min NO inhalation trial. The conclusions of this study were extremely limited, however, since pulmonary artery pressure was not measured, and only 7% of the initially evaluated premature infants were included in the study. There is concern that an inhibitory effect of NO on platelet aggregation might contribute to the occurrence of intracranial hemorrhages in premature infants (Meurs *et al.*, 1997). An increased rate of bleeding complications has been noted in term infants (Neonatal Inhaled Nitric Oxide Study Group, 1997b), but insufficient data have been published to confirm the safety of inhaled NO therapy in premature newborns. In neonatal lung diseases characterized by abnormal lung development, such as congenital diaphragmatic hernia (Neonatal Inhaled Nitric Oxide Study Group, 1997b), inhaled NO appears to be less effective or without benefit.

Acute Respiratory Distress Syndrome

Pulmonary Vascular Resistance

Rossaint *et al.* (1993) demonstrated that inhaled NO produced selective pulmonary vasodilation in patients with severe ARDS (Fig. 2). This was later confirmed by larger studies (Dellinger *et al.*, 1998; Manktelow *et al.*, 1997). In some patients, NO-induced pulmonary vasodilation was sufficient to improve right ventricular performance (Rossaint *et al.*, 1995a). In children with ARDS, inhaled NO (20 ppm) decreased mean pulmonary artery pressure (MPAP) by 25% and increased cardiac index by 14% (Abman *et al.*, 1994). Inhaled NO also effectively relieved the pulmonary hypertension associated with the use of permissive hypercapnia in patients with ARDS (Puybasset *et al.*, 1994).

Inhaled NO (40 ppm) decreased pulmonary capillary pressure (Benzing and Geiger, 1994) and pulmonary trans-

Figure 2 Mean pulmonary artery pressure (PAP), arterial oxygenation efficiency ($\text{PaO}_2/\text{FiO}_2$), and venous admixture (Q_s/Q_T) during inhalation of 18 and 36 ppm nitric oxide in nine patients with adult respiratory distress syndrome. Solid symbols represent patients treated with extracorporeal membrane oxygenation. Reproduced with permission from Rossaint *et al.* (1993).

vascular albumin flux (Benzing *et al.*, 1995) in patients with acute lung injury, partly due to reducing pulmonary venous resistance (Benzing and Geiger, 1994). Reductions of pulmonary venous and pulmonary capillary pressure should promote the resolution of pulmonary edema.

Arterial Oxygenation

Severe hypoxemia is characteristic of ARDS. Common current strategies of management include lung recruitment by high levels of positive end-expiratory pressure, prone positioning, and ventilation with a high FiO_2 . Therapies that permit lower airway pressures and FiO_2 might reduce the risk of barotrauma and oxidant injury to the lung. In initial clinical studies, inhaling 18 ppm NO for 40 min reduced the shunt fraction by 5% and increased the $\text{PaO}_2/\text{FiO}_2$ ratio by 30% in patients with ARDS (Rossaint *et al.*, 1993). In a dose-ranging study of ARDS patients breathing NO, the ED_{50} (the dose producing 50% of maximal effect) for increasing the partial pressure of oxygen in arterial blood (PaO_2) was markedly less [10 to 100 parts per billion (ppb)] than the ED_{50} producing pulmonary vasodilation (1–10 ppm, see Fig. 3) (Gerlach *et al.*, 1993).

In a Phase II multicenter trial, the effects of NO inhalation were studied in 177 patients with ARDS ($\text{PaO}_2/\text{FiO}_2 < 200$ mmHg within the last 72 hours, bilateral chest infiltrates, pulmonary capillary wedge pressure < 18 mmHg, requirement for positive end-expiratory pressure (PEEP) > 8 cm H_2O , and FiO_2 requirement > 0.5) (Dellinger *et al.*, 1998). Sixty-five percent of the patients who received inhaled NO (pooled results of patients receiving either 1.25, 5, 20, 40, 40, or 80 ppm NO) had a significant improvement in PaO_2 (defined as a 20% increase of PaO_2 after 4 hours of therapy). Only 24% of the patients receiving placebo (nitrogen) responded similarly (see Fig. 4). The improved oxygenation induced by NO allowed physicians to decrease FiO_2 and PEEP and thereby decreased the oxygenation index [$(\text{FiO}_2 \times \text{mean airway pressure} \times 100)/\text{PaO}_2$] for the first 4 days of therapy. The MPAP remained modestly lower in the inhaled NO group, compared with placebo, for 2 days. Similar transient improvements of $\text{PaO}_2/\text{FiO}_2$ during inhaled NO therapy in patients with ARDS have been demonstrated in prospective studies conducted by Michael *et al.* (1998) and Troncy *et al.* (1998).

Some patients do not respond to NO inhalation with pulmonary vasodilation and improved oxygenation. In studies of critically ill patients with ARDS who were ventilated with low concentrations of NO gas (< 40 ppm), approximately 35% of patients have minimal or no response to inhaled NO. Varying responses to NO inhalation are also observed among different patients and during the course of acute lung injury in individual patients (Bigatello *et al.*, 1994; Lundin *et al.*, 1996, 1997; Mira *et al.*, 1994; Rossaint *et al.*, 1995b; Wysocki *et al.*, 1994). The precise mechanism for the variable responsiveness to NO is unknown. Clinicians are thus unable to accurately predict the responsiveness of individual patients to inhaled NO. In general, the baseline level of PVR appears to predict the degree of pulmonary vasoconstriction reversible by NO inhalation. Those with the greatest degree of pulmonary hypertension respond maximally to NO inhalation (Bigatello *et al.*, 1994; Puybasset *et al.*, 1995; Young *et al.*, 1994). A favorable response to inhaled NO may be related to the degree of alveolar recruitment (Putensen *et al.*,

Figure 3 Dose-response to inhaled NO for PaO₂ (top) and mean pulmonary arterial pressure (bottom) in 12 patients with ARDS. The estimated ED₅₀ (the dose producing 50% of maximal effect) for PaO₂ increase was 0.11 ppm and the estimated ED₅₀ for mean pulmonary artery pressure (PPA) decrease was 1.2 ppm. Values are means \pm SD. Reprinted with permission from Gerlach *et al.* (1993).

Figure 4 Percentage of ARDS patients who respond with a PaO₂ increase of 20% or more while receiving 0–40 ppm NO during a 4-hour inhalation period. Reprinted with permission from Dellinger *et al.* (1998).

1994; Puybasset *et al.*, 1995). Ventilatory techniques that increase alveolar recruitment, such as the use of high-frequency oscillation in neonates (Kinsella *et al.*, 1997), or prone positioning of ARDS patients (Papazian *et al.*, 1998a), may improve the response to inhaled NO. Enhancing pulmonary vasoconstriction while administering inhaled NO may accentuate the improvement in PaO₂ observed during inhaled NO therapy, presumably by improving \dot{V}/\dot{Q} matching. The concomitant intravenous infusion of a vasocon-

stricting drug, almitrine, which increases the degree of hypoxic vasoconstriction in the lung, has been reported to enhance the beneficial effect of inhaled NO on PaO₂ (Payen *et al.*, 1993; Wysocki *et al.*, 1994). The concomitant infusion of norepinephrine during inhaled NO therapy appears to have a similar beneficial effect in septic patients with ARDS (Papazian *et al.*, 1998b).

Outcome

Early placebo-controlled trials of inhaled NO to treat ARDS have been disappointing, because they demonstrated only transient improvements in oxygenation (several days) and have failed to demonstrate an improved outcome. The Phase II U.S. multicenter study of the effects of inhaled NO on ARDS patients, discussed earlier, reported a mortality rate of 30% in both NO (all doses pooled) and placebo treated patients (Dellinger *et al.*, 1998). The patients were randomly assigned to receive 1.25, 5, 20, 40, or 80 ppm NO or nitrogen (N₂) placebo. Subgroups receiving the same dose of NO for the treatment period consisted of 8–34 patients. This severely limited the power of the study. The mortality rates in the subgroups were not statistically different: 32% (7/22 patients) in the 1.25 ppm group, 24% (8/24 patients) in the 5 ppm group, 31% (9/29) in the 20 ppm group, 30% (8/27 patients) in the 40 ppm group, and 38% in the 80 ppm group. A prospective randomized study reported by Troncy and associates (1998) similarly found no significant difference between ARDS patients receiving inhaled NO and controls with regard to 30-day mortality or days of mechanical

ventilation, but the small sample size (15 patients in each group) severely limited the power of the study to detect significant differences.

Are the beneficial effects of inhaled NO insufficient to alter outcome? Decreased pulmonary capillary pressure should decrease the extent of pulmonary edema, should improve lung compliance, and might improve resolution of lung injury. Improved oxygenation should permit a reduction of FiO_2 and airway pressure. If high airway pressures were being used, lower airway pressures could reduce barotrauma.

Although attractive, proving such hypotheses is difficult. The pulmonary artery pressure is usually only modestly elevated in ARDS. Even in the severe ARDS, the mean pulmonary artery pressure is usually about 30 mmHg (Zapol and Snider, 1977). This degree of pulmonary hypertension is usually well tolerated, and few patients with ARDS die of acute pulmonary hypertension.

Importantly, with the use of ventilatory strategies that are currently popular, in which airway pressures are limited to avoid pulmonary overdistention, slightly reducing airway pressure in patients with a moderate degree of lung injury may not improve outcome (Stewart *et al.*, 1998). Indeed, a worsened outcome might occur if NO-induced improvements in oxygenation are offset by prematurely reducing the level of positive end-expiratory pressure. Such reductions in PEEP can result in alveolar derecruitment and perhaps increased shear stress and barotrauma during mechanical ventilation (Amato *et al.*, 1998; Lachmann, 1992). Such premature derecruitment could explain the transitory nature of the improvement in $\text{PaO}_2/\text{FiO}_2$ noted in several prospective studies (Dellinger *et al.*, 1998; Michael *et al.*, 1998; Troncy *et al.*, 1998).

Improvements in oxygenation alone may not be sufficient to alter the clinical outcome of a population of ARDS patients. The survival rate of patients with ARDS appears to depend more on the occurrence of sepsis and multiple organ failure than on gas exchange. The majority of ARDS patients die from severe sepsis or multiple organ failure rather than refractory hypoxemia (Montgomery *et al.*, 1985; Suchyta *et al.*, 1992). It is unknown if patients with severe life-threatening hypoxemia would benefit from inhaled NO because such patients have been excluded from prospective studies.

The effect of inhaled NO varies among patients. Approximately one-third of patients fail to demonstrate a significant improvement in oxygenation or reductions of pulmonary artery pressure (Dellinger *et al.*, 1998; Manktelow *et al.*, 1997). Nevertheless, such patients must be included in studies that place subjects in the experimental or placebo group on an "intention to treat" basis. In addition, protocols may select a single fixed dose to administer. Such designs assume that the dose-response relationship of inhaled NO is similar among ARDS patients and over time. This may not be true (Gerlach *et al.*, 1999).

The beneficial effects of NO inhalation may be offset by its toxic effects. Doses as high as 80 ppm have been

evaluated in both pediatric and adult studies. In experimental studies of ischemia-reperfusion injury during lung transplantation, low doses of inhaled NO were protective, but high doses were not (Murakami *et al.*, 1996). Before such studies, it was not well appreciated that the beneficial effects of inhaled NO could be lost at higher doses. The dose for NO inhalation may therefore have a narrow therapeutic range. Small doses, for example, 1–5 ppm, could be effective and improve survival; very low doses might be not effective, and larger doses could be toxic.

Lastly, the patients included in studies of ARDS rarely have a single disease of uniform severity. This might increase the heterogeneity of response or benefit to NO. The response to inhaled NO may be confounded by many factors including sepsis, excessive endogenous NO production, or a lack of endogenous production.

Performing such trials is difficult and expensive. The incidence of ARDS is relatively low, and the precipitating events are often multifactorial. Usually a large number of centers must participate to recruit sufficient numbers of patients. There may be significant differences in response rates and outcomes among different centers, as reported for PPHN patients by Kinsella *et al.* (1997). Different treatment strategies and the experience of individual institutions and caregivers may provide confounding variables. Study of well-defined subgroups of patients, such as those with marked pulmonary hypertension following lung injury or cardiac surgery, may be more successful.

Lung Transplantation

Inhaled NO may provide selective pulmonary vasodilation for both the native and transplanted lung and may reduce the necessity for cardiopulmonary bypass of the recipient during lung transplantation. Data from experimental animal studies suggest that reperfusion injury in lung transplantation may be reduced by the administration of inhaled NO (Bacha *et al.*, 1996; Murakami *et al.*, 1996). While patient studies evaluating the ability of inhaled NO to affect reperfusion injury have not been published yet, inhaled NO has been used to episodically treat the pulmonary artery hypertension that sometimes occurs immediately following lung transplantation (Adatia *et al.*, 1994). Inhaled NO also has been used to treat pulmonary dysfunction following transplantation. In a retrospective study by Date *et al.* (1996), 243 lung transplantations over 6 years were analyzed. Thirty-two patients had immediate severe graft dysfunction, as indicated by a $\text{PaO}_2/\text{FiO}_2$ ratio < 150 mmHg. Comparing patients in whom NO treatment was not available with later patients in whom NO treatment was begun after graft dysfunction was diagnosed, inhaled NO reduced MPAP and increased the $\text{PaO}_2/\text{FiO}_2$ ratio within the first hour of treatment. The requirement of ECMO was similar in both patient groups. Inhaled NO therapy appeared to reduce the rate of airway complications and hospital mortality (7% in NO group versus 24% in control group) in this patient pop-

ulation. Although this study suggests that inhaled NO may decrease pulmonary dysfunction following lung transplantation, as in all retrospective studies using historical controls, changes of treatment strategies and increased clinical experience over time must be considered.

Cardiac Surgery

Inhaled NO is widely used as a selective pulmonary vasodilator for cardiac surgical patients. Inhaled NO has been used to determine pulmonary vascular reactivity and the necessity for heart–lung versus lung transplantation alone (Adatia *et al.*, 1995). The successful intraoperative use of inhaled NO has been described in small case series (Fullerton *et al.*, 1996; Rich *et al.*, 1993). Postoperatively, inhaled NO has been used to treat RV dysfunction associated with pulmonary hypertension (Argenziano *et al.*, 1998; Wagner *et al.*, 1997).

Why is inhaled nitric oxide especially attractive for use in cardiac disease? Unlike intravenous pulmonary vasodilators, inhaled NO can reduce pulmonary vascular resistance while maintaining the coronary perfusion pressure. Although right ventricular (RV) dysfunction is relatively rare and often transient, its occurrence is catastrophic. Maintenance of aortic pressure and right coronary artery perfusion pressure is extremely critical in the presence of RV dysfunction (Hurford and Zapol, 1988).

The degree and reversibility of the preexisting pulmonary hypertension determine the various treatment options and outcome in children with congenital heart disease and PAH (Haworth, 1984). Roberts *et al.* (1993) demonstrated that inhaled NO (80 ppm for 10 min) decreased MPAP without causing systemic vasodilation in children between 3 months and 7 years of age with congenital cardiac lesions (e.g., atrioseptal defect, ventricular septal defect, atrioventricular canal). The ability of inhaled NO to decrease the PVR of children with congenital cardiac defects has been confirmed by others (Allman *et al.*, 1996; Berner *et al.*, 1996). In preoperative patients with severe right-to-left shunting, inhaled NO increases pulmonary blood flow, decreases extrapulmonary shunt flow, and improves oxygenation (Roze *et al.*, 1994). Chronic administration of inhaled NO therefore might be useful in the perioperative management of these patients.

After cardiopulmonary bypass, transient PAH is common and has been related to damage to the pulmonary vascular endothelium (Wessel *et al.*, 1994). Inhaled NO has been reported to ameliorate the postoperative PAH of congenital heart disease (Curran *et al.*, 1995; Journois *et al.*, 1994; Miller *et al.*, 1994) and decrease the need for postoperative ECMO (Goldman *et al.*, 1996a). Similar findings have been reported in adults following cardiac surgery for coronary artery or valvular disease (Fullerton *et al.*, 1996; Rich *et al.*, 1993).

Inhaled NO has been used to treat cardiac failure requiring a left ventricular assist device (LVAD) (Argenziano *et*

al., 1998; Wagner *et al.*, 1997). When an LVAD is used, systemic blood flow is directly dependent on pulmonary vascular resistance; a reduction of pulmonary resistance increases blood flow delivery to the LVAD and cardiac output. A similar physiological situation exists after a Fontan procedure, after which NO has also been reported to effectively increase cardiac output (Goldman *et al.*, 1996b).

In cardiac transplantation, small case series have documented that inhaled nitric oxide can reduce pulmonary vascular resistance and that sometimes this effect can be substantial (Kieler-Jensen *et al.*, 1994). In a study of patients following heart transplantation, inhalation of 20 ppm NO caused significant pulmonary vasodilation, but also decreased systemic vascular resistance (Auler *et al.*, 1996). The decreased systemic vascular resistance was most likely secondary to an improved cardiac output, since systemic arterial pressure and pulmonary capillary wedge pressure remained unchanged.

Chronic Lung Disease

Chronic Pulmonary Hypertension

PATHOPHYSIOLOGY

The pathophysiology of chronic PAH includes a partially reversible increase of MPAP in the early stages of the disease, leading to a nonreactive and irreversibly remodeled pulmonary vasculature after long-standing PAH (Meyrick and Reid, 1983). Vascular remodeling is characterized by muscularization of previously nonmuscular small resistance arteries, medial hypertrophy of proximal pulmonary arteries, and a reduced number of arteries within the lung. Endothelial-dependent relaxation may be impaired (Cremona *et al.*, 1991; Dinh Xuan *et al.*, 1990, 1991). Diagnosis and medical treatment of chronic PAH relies on vasodilator therapy. When medical treatment is not effective, lung transplantation remains as the last option to prolong life (Rich, 1998).

EVALUATION

The determination of pulmonary vascular responsiveness is essential for prognosis and long-term treatment. Drugs commonly used to assess pulmonary vasodilatory responses include intravenous prostacyclin (PGI₂), adenosine, and calcium-channel blockers (Kneussl *et al.*, 1996). The acute reduction of pulmonary vascular resistance in response to inhaled nitric oxide in such patients corresponds to the acute response to other vasodilators such as prostacyclin (Fig. 5) (Channick, 1999; Pepke-Zaba *et al.*, 1991). The pulmonary vascular response to inhaled NO is useful in the cardiac catheterization laboratory to suggest which patients may have pulmonary vascular recruitability and may respond to long-term vasodilator therapy. Because inhaled NO does not cause systemic hypotension during such therapeutic trials, its use could be safer, compared with intravenous or oral vasodilators (Sitbon *et al.*, 1995). Despite the investigational status of the drug, its use to test pulmonary vascular responsiveness

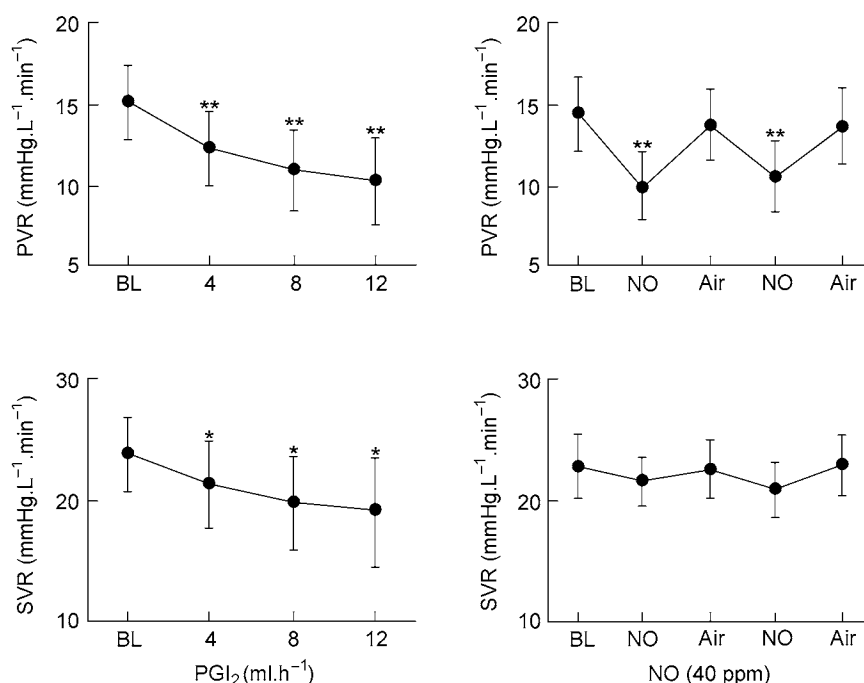

Figure 5 Pulmonary (PVR) and systemic (SVR) vascular resistance in eight patients with pulmonary hypertension receiving an intravenous infusion of prostacyclin (PGI₂) (0.5 mg in 250 ml) at rates of 4, 8, and 12 ml/hour, or inhalation of 40 ppm NO in air. Inhaled NO produced selective pulmonary vasodilation. Values are means \pm SEM. * $p < 0.05$; ** $p < 0.01$. Reproduced with permission from Pepke-Zaba, J., Higenbottam, T. W., Dinh-Xuan, A. T., Stone, D., and Wallwork, J., Inhaled nitric oxide as a cause of selective pulmonary vasodilatation in pulmonary hypertension, Volume 338, pp. 1173–1174, © by The Lancet Ltd., 1991.

has been recommended (Fishman *et al.*, 1998), and a survey of long-term vasodilator treatment in patients with primary pulmonary hypertension reported that inhaled NO was used as the primary vasodilator to test pulmonary vascular responsiveness in 32% of the responding tertiary hospitals in the United States (Robbins *et al.*, 1998).

MANAGEMENT

In chronic PAH, a positive response to a short-term vasodilator trial usually results in continuing vasodilator therapy that may include a variety of systemic drugs (e.g., angiotensin converting enzyme inhibitors, calcium channel blockers, prostacyclin) and permanent anticoagulation. The efficacy of current vasodilator treatment is often limited by systemic hypotension.

On demand NO delivery devices to be used with nasal cannulas have been developed for chronic ambulatory treatment of patients intolerant to conventional vasodilators (Channick *et al.*, 1996). Channick (1999) has described chronic ambulatory administration inhaled NO for 13 weeks to 3 years in seven patients. There appears to be a durable, subjective response, pulmonary artery pressure decreases over time; and no adverse effects have been observed. The mechanism of action remains uncertain. Long-term domiciliary NO inhalation as a bridge or alternative to lung-transplantation requires investigation in larger patient groups, after better delineation of the beneficial and toxic effects

caused by long-term NO inhalation (Goldman *et al.*, 1995; Snell *et al.*, 1995).

Obstructive Airway Disease

Chronic obstructive pulmonary disease (COPD) is characterized by irreversible airway obstruction, associated with irregular enlargement of alveoli and destruction of alveolar walls after chronic inflammation. Hypoxia produces pulmonary vasoconstriction, resulting in chronic PAH and right ventricular hypertrophy. Hypoxemia in COPD is primarily caused by a \dot{V}/\dot{Q} mismatch, and not by intrapulmonary right-to-left shunting (as in ARDS). Hypoxic pulmonary vasoconstriction partially diverts blood flow from poorly ventilated regions and improves oxygenation. The administration of inhaled NO may oppose this effect. Inhaled nitric oxide may reach and have a prolonged residence time within partially obstructed, poorly ventilated lung regions. Release of hypoxic pulmonary vasoconstriction within these areas could worsen the matching of ventilation to perfusion (Hopkins *et al.*, 1997). Consequently, during air breathing, nitric oxide inhalation may worsen arterial oxygenation in patients with COPD (Barabrà *et al.*, 1996; Katayama *et al.*, 1997). When hypoxic pulmonary vasoconstriction is relieved by moderate concentrations of oxygen in such patients, however, the concomitant administration of inhaled NO increases PaO₂ and decreases MPAP to a greater extent than with O₂ therapy

alone (Yoshida *et al.*, 1997a). Inhaled nitric oxide has been demonstrated to prevent exercise-induced oxygen desaturation in patients with severe COPD (Roger *et al.*, 1997). This effect may be due to alterations of \dot{V}/\dot{Q} distribution or the pattern of NO delivery. Patients with idiopathic pulmonary fibrosis who have both severe pulmonary artery hypertension and hypoxemia may benefit from inhaled NO, especially when it is combined with oxygen treatment (Yoshida *et al.*, 1997b).

Treatment of Bronchoconstriction

Inhaled NO has been reported to be a bronchodilator in many experimental animal models. Högman *et al.* (1993a) examined inhalation of 80 ppm NO in healthy volunteers, in patients with hyperreactive airways, bronchial asthma, and COPD. Inhaled NO caused mild bronchodilation in patients with asthma but not in COPD patients. In other studies, however, the bronchodilator action of NO has been reported to be much weaker than commonly used inhaled β_2 -adrenergic agonists (Kacmarek *et al.*, 1996; Pfeffer *et al.*, 1996; Sanna *et al.*, 1994).

High-Altitude Pulmonary Edema

Severe (hypoxic) pulmonary vasoconstriction and hypertension characterize high-altitude pulmonary edema (HAPE). Scherrer *et al.* (1996) hypothesized that inhalation of NO would reduce MPAP and thus the severity of HAPE. Nitric oxide (40 ppm), inhaled at high altitude (4559 m), decreased MPAP in both subjects prone to HAPE and those with HAPE, but not in HAPE-resistant control subjects. In subjects with HAPE, perfusion scintigraphy demonstrated that inhaled NO redistributed pulmonary blood flow from edematous to nonedematous lung regions. This was associated with an improved PaO_2 .

Effect on Blood Elements and Endothelial Cells

Sickle Cell Disease

Homozygous sickle cell anemia is a genetic disease characterized by severe hemolytic anemia, frequent vaso-occlusive events and a reduced life expectancy. A single amino acid substitution from valine to glutamic acid of the hemoglobin β -chain results in hemoglobin S (HbS) formation. On deoxygenation, a red blood cell containing HbS changes its shape from a biconcave disk into a crescent-shaped sickle cell due to intracellular hemoglobin polymerization. Sickle cells can occlude the microcirculation (Steinberg, 1996).

HbS has a markedly decreased O_2 affinity, reflected by an increased P_{50} (partial pressure of O_2 at half saturation of hemoglobin), compared with adult hemoglobin. In studies by Head *et al.* (1997), inhalation of 80 ppm NO for 45 min by patients with homozygous sickle cell disease shifted their

blood O_2 dissociation curve 4.6 ± 2.0 mmHg to the left, significantly decreasing the P_{50} (see Fig. 6). Significant methemoglobinemia did not occur. In five of seven volunteers with sickle cell disease, the effect persisted for at least 60 min after discontinuing NO. In normal volunteers, the P_{50} was not affected by breathing NO. Precisely how inhaled NO alters sickle hemoglobin is unknown. One hypothesis is that the Cys- β 93 residue of HbS is modified by NO, increasing HbS solubility and decreasing the tendency to polymerize on deoxygenation (Garel *et al.*, 1986; Schechter, 1997).

Other Effects

In experimental models, inhaled NO has been reported to display many actions with potential clinical importance, including inhibition of platelet adhesion and aggregation (Adrie *et al.*, 1996; Gries *et al.*, 1997; Högman *et al.*, 1993b, 1994; May *et al.*, 1991; Samama *et al.*, 1995), inhibition of leukocyte infiltration and inflammation (May *et al.*, 1991; Niu *et al.*, 1994; Provost *et al.*, 1994), inhibition of superoxide production and scavenging of oxygen free radicals (Clancy *et al.*, 1992; Hassoun *et al.*, 1995; Kanner *et al.*, 1991; Kavanagh *et al.*, 1994; Wink *et al.*, 1993), reduction of oxygen toxicity (McElroy *et al.*, 1997), and attenuation of vascular damage and smooth muscle proliferation (Cornwell *et al.*, 1994; Kouyoumdjian *et al.*, 1994; Roberts *et al.*, 1995). The clinical importance of these actions of NO remains to be fully explored.

Toxicity of Nitric Oxide Inhalation Therapy

Direct Toxicity

At high inspired levels, nitric oxide is directly toxic to tissues. An acute inhaled NO overdose (>500 – 1000 ppm) leads to rapid nitrogen dioxide (NO_2) formation, severe methemoglobinemia, pulmonary edema and alveolar hemorrhage, hypoxemia, and death within minutes to hours (Clutton-Brock, 1967; Greenbaum *et al.*, 1967). High levels of nitric oxide are also present in cigarette smoke (Norman and Keith, 1965). These levels, although much greater than the concentrations being considered for clinical use, are tolerated for short periods by millions of smokers. High levels of nitrogen dioxide production can be problematic with some delivery systems (Nishimura *et al.*, 1995), but very low inspired levels have been reported in randomized trials (Dellinger *et al.*, 1998). Commercial delivery systems and medical grade sources of NO gas have been developed, and inhaled NO doses of ≤ 20 ppm are commonly used (Kirmse *et al.*, 1998). Consequently, NO_2 levels have been kept at low levels.

Little is known about the long-term sequelae of NO inhalation in humans. In 12 newborns receiving NO inhalation treatment (<20 ppm) for up to 4 days, there were no signs of increased lipid peroxidation products, impaired surfactant activity, or changed cytokine profile (Hallman *et al.*, 1998).

Figure 6 Effects of NO on oxygen affinity of red blood cells. Exposure to NO (80 ppm for 15 min) shifted to the left the oxygen dissociation curve of hemoglobin S erythrocytes (left). The effect of NO exposure on P₅₀ of hemoglobin S erythrocytes was dose dependent (right). Values are means \pm SE. Reprinted with permission from Head *et al.* (1997).

Nitrotyrosine residues were detected in the airway specimens of two infants requiring prolonged ventilation with NO in this study. The relative contribution of NO inhalation and endogenous NO formation to nitrotyrosine formation in the lung is unclear, however, because nitrotyrosine formation has been demonstrated in acutely injured lungs without the exogenous administration of NO (Haddad *et al.*, 1994; Kooy *et al.*, 1995). Studies of survivors of ARDS treated with inhaled NO reported no obvious differences in pulmonary function compared with ARDS patients not treated with NO (Luhr *et al.*, 1998). The doses of NO in current clinical use are less than that received with cigarette exposure and are nearly within the range encountered while breathing the air of many urban centers (Lee *et al.*, 1997).

Methemoglobinemia

Blood methemoglobin concentrations have been regularly monitored in clinical trials of inhaled NO in adults and neonates (Dellinger *et al.*, 1998; Kinsella *et al.*, 1997; Neonatal Inhaled Nitric Oxide Study Group, 1997a,b; Roberts *et al.*, 1997). The incidence of methemoglobinemia has been low. Its occurrence is more common in neonates and with high inhaled doses, but it is usually well tolerated. There have been no reports of sequelae to methemoglobinemia in randomized studies. Methemoglobinemia is easily treated by reducing the dose of NO. Single reported cases of more severe methemoglobinemia during NO therapy have occurred in the setting of high doses (Hess *et al.*, 1997). Chemical therapies, such as methylene blue and ascorbic acid, are available, but they should not be necessary if methemoglobin levels are monitored.

Inhibition of Platelet Function

Inhaled NO inhibits platelet function. Increased bleeding times and decreased platelet aggregation have been reported in experimental animals and patients (George *et al.*, 1998; Högman *et al.*, 1993b, 1994; Samama *et al.*, 1995). In randomized studies of adults and term and nearly full-term infants, however, an increased incidence of clinical bleeding

has not been substantiated (Dellinger *et al.*, 1998; Kinsella *et al.*, 1997; Neonatal Inhaled Nitric Oxide Study Group, 1997a,b; Roberts *et al.*, 1997). Indeed, platelet inhibition could be therapeutic, rather than detrimental. Nevertheless, a cautious approach to the possibility of worsened bleeding during inhaled NO therapy remains prudent, especially in premature infants who have a high incidence of intracranial hemorrhages (Meurs *et al.*, 1997).

Adverse Hemodynamic Effects

Inhaled NO may also have adverse hemodynamic effects. Inhalation of NO may vasodilate the pulmonary circulation and increase blood flow entering the left ventricle. In patients with preexisting severe left ventricular dysfunction, an increased left ventricular end-diastolic pressure (Hayward *et al.*, 1996; Loh *et al.*, 1994; Semigran *et al.*, 1994) and pulmonary edema (Bocchi *et al.*, 1994) during NO breathing have been reported. This increase may be due to small increases in left ventricular volume associated with improved right ventricular function that, in turn, produced exaggerated increases in pulmonary capillary wedge pressure when the left ventricle is poorly compliant. Monitoring of left ventricular function may be indicated when inhaled NO is administered to patients with severe left ventricular dysfunction.

Rebound hypoxemia and pulmonary hypertension may occur after the sudden discontinuation of NO (Bigatello *et al.*, 1994; Lavoie *et al.*, 1996; Rossaint *et al.*, 1993). It has been suggested that the downregulation of endogenous NO synthesis by NO inhalation is responsible for rebound PAH (Ma *et al.*, 1996; Rengasamy and Johns, 1993). Data obtained in rats with hypoxic pulmonary hypertension, however, suggest that inhibition of endogenous NO synthesis play a minor role in rebound PAH: no changes of lung endothelial nitric oxide synthase (NOS) protein levels, NOS activity, endothelium-dependent and -independent vasodilation were reported after 3 weeks inhaling 20 ppm NO. Lung guanylate cyclase activity was transiently decreased after 1 week of NO inhalation, but guanylate cyclase activity was normal after 3 weeks of NO inhalation (Frank *et al.*, 1998).

Rebound hypoxemia and pulmonary hypertension can be anticipated, and attenuated by increasing the FiO_2 , and, perhaps, through the administration of phosphodiesterase inhibitors (Hess *et al.*, 1997). The administration of a type V phosphodiesterase inhibitor, dipyridamole, has been reported to prevent rebound PAH following discontinuation of inhaled NO (al-Alaiyan *et al.*, 1996; Ivy *et al.*, 1998; Ziegler *et al.*, 1998).

Summary

Inhaled NO offers a novel therapy for the treatment of pulmonary hypertensive diseases and the symptomatic relief of hypoxemia. The use of inhaled NO reduces the necessity for ECMO in newborns and infants with acute hypoxemic respiratory failure. Proper indications, contraindications, dosing criteria, and implications of the toxic actions of NO remain to be fully delineated. Randomized clinical studies of patients with carefully defined specific acute disease states characterized by pulmonary hypertension or hypoxemia (e.g., pulmonary embolism, severe PAH, postpneumonectomy pulmonary edema, acute rejection following lung transplantation) and of premature newborns with respiratory failure remain to be completed. If such trials are carefully designed and conducted, we may define additional groups of patients that may benefit from, or may be harmed by, inhaled NO. Chronic ambulatory inhaled NO therapy may someday prove valuable for patients with pulmonary hypertension. The use of inhaled NO continues to be a unique and fascinating approach to studying and treating diseases as diverse as acute rejection of the transplanted lung and sickle cell crisis.

DIRECT MEASUREMENTS OF NITRIC OXIDE (NO) IN BIOLOGICAL TISSUES ARE DIFFICULT TO PERFORM BECAUSE THIS GAS REACTS RAPIDLY WITH HEMOGLOBIN OR OTHER PROTEINS. THEREFORE, ONE MUST OFTEN RELY ON INDIRECT METHODS IN ORDER TO DETECT NO SYNTHESIS *IN VIVO*. THESE INCLUDE ANALYSIS OF NITRATE/NITRITE OR CITRULLINE, IMMUNO-HISTOCHEMICAL DETECTION OF NITRIC OXIDE SYNTHASE (NOS), AND FUNCTIONAL STUDIES USING NOS INHIBITORS. UNLIKE THE SITUATION IN MOST BIOLOGICAL TISSUES, WHERE NO IS RAPIDLY METABOLIZED, NO IN THE GAS PHASE IS FAIRLY STABLE, ESPECIALLY AT LOW CONCENTRATIONS (BODY *ET AL.*, 1995). THEREFORE, NO PRODUCED IN SUPERFICIAL STRUCTURES OF HOLLOW ORGANS WILL DIFFUSE TO THE LUMEN AND MAY THUS BE DETECTABLE IN GAS COLLECTED FROM SUCH ORGANS. IN THIS CHAPTER WE WILL DISCUSS MEASUREMENTS OF LUMINAL NO IN THE AIRWAYS, GASTROINTESTINAL, AND UROGENITAL TRACTS AND ITS PHYSIOLOGICAL RELEVANCE IN HEALTH AND DISEASE.

Airways

The presence of NO in the exhaled breath of animals and humans was first demonstrated by Gustafsson *et al.* in 1991. The expired NO was detected in the low parts per billion (ppb) range with a chemiluminescence technique as well as with mass spectrometry, and it was decreased on intravenous (i.v.) administration of a NOS inhibitor. The chemiluminescence technique uses an excess of ozone (O₃), which reacts with NO to produce nitrogen dioxide (NO₂*) with an electron in an excited energy level. NO₂* changes back to the ground state while emitting electromagnetic radiation ranging between 600 and 3000 nm in wavelength. A photomultiplier tube proportionally converts the intensity of lu-

minescence into an electrical signal (Archer, 1993; Fontijn *et al.*, 1970). The chemiluminescence technique is highly sensitive, and NO can be detected down to parts per trillion levels. Early studies showed that in healthy humans, basically all NO found in exhaled air originates from the upper airways, with only a minor contribution from the lower respiratory tract and the lungs (Alving *et al.*, 1993; Lundberg *et al.*, 1994; Gerlach *et al.*, 1994). Conscious tracheostomized subjects exhaled only low levels when breathing through the tracheostomy, whereas much higher levels were seen during oral or nasal breathing (Lundberg *et al.*, 1994a). In all healthy subjects, NO values are higher during nasal than during oral breathing, indicating a large NO release in the nasal airways (Alving *et al.*, 1993; Lundberg *et al.*, 1994a).

Figure 1 Immunohistochemical staining of inducible NOS (iNOS) in human paranasal sinus mucosa from a healthy individual showing intense signal apically in the epithelial cells. From Lundberg *et al.* (1995a) with permission.

NO in the Upper Airways

At present the precise origin of the NO in the upper airways and the relative contribution from different sources within the nasal airways are not known. There is a large production of NO in the paranasal sinuses in adult healthy humans (Lundberg *et al.*, 1995a). Air aspirated directly from the human sinuses contains NO in concentrations of 10–30 parts per million (ppm), which is similar to the highest permissible atmospheric pollution levels (Lundberg *et al.*, 1995a). NO release in the sinuses is markedly reduced by intrasinus instillation of the NO synthase inhibitor *N*^G-nitro-L-arginine methyl ester (L-NAME) (Lundberg *et al.*, 1995a). Immunohistochemical (Fig. 1) and *in situ* hybridization studies show dense staining for NOS and its mRNA in sinus epithelium (Lundberg *et al.*, 1995a). Nasal NO levels are markedly reduced in patients who generally have mucus-filled paranasal sinuses and obstructed sinus ostia (Kartagener's syndrome) (Lundberg *et al.*, 1994a), cystic fibrosis (Lundberg *et al.*, 1996a), and acute sinusitis (Baraldi *et al.*, 1997), indicating a normal contribution from the paranasal sinuses to nasally measured NO (Fig. 2). Interestingly, nasal NO levels are high in humans and other primates (Schedin *et al.*, 1997) but very low in baboons (Lewandowski *et al.*, 1998), the only mammal lacking paranasal sinuses.

Both immunohistochemical and *in situ* hybridization studies indicate that the NOS found in healthy sinus epithelium (Lundberg *et al.*, 1995a) is identical to or very closely related to the inducible NOS (iNOS) that has been cloned from activated human hepatocytes (Geller *et al.*, 1993). Moreover, NOS activity in sinus mucosa is predominantly calcium independent, which is an attribute associated with iNOS (Lundberg *et al.*, 1996b). However, the regulation of the expression and the activity of sinus NOS seems to differ from what has previously been described for iNOS. Thus,

sinus NOS is constantly expressed and seems to be resistant to steroids (Lundberg *et al.*, 1995a, 1996b), properties that are normally associated with the low-rate NO-producing endothelial and neuronal forms of NOS. Immunohistochemistry for NOS in the nasal mucosa has shown only weak staining for iNOS (Lundberg *et al.*, 1995a). Moreover, Ramis *et al.* (1996) found only calcium-dependent NOS activity in nasal mucosa from healthy subjects. However, human nasal epithelium from patients with nasal polyp disease expresses increased iNOS mRNA compared to normal epithelium (Watkins *et al.*, 1998). Nasal NO levels are only slightly reduced following topical administration of L-NAME, whereas the same inhibitor at lower concentrations caused a marked decrease in sinus NO output (Lund-

Figure 2 Nasal nitric oxide levels in various disorders involving the paranasal sinuses compared to healthy controls. Data from Lundberg *et al.* (1994a, 1996a), Lindberg *et al.* (1997a), and Arnal *et al.* (1999).

berg *et al.*, 1995a). Taken together these findings indicate that the nasal mucosa may not be a major source of NO in the upper airways.

NASAL NO MEASUREMENTS

Several techniques for collecting nasal air have been used. The most commonly presented way to measure nasal NO is to sample nasal air directly from one nostril (Lundberg *et al.*, 1996c; Kharitonov *et al.*, 1997a; ATS Taskforce, 1999). Using the intrinsic flow of the chemiluminescence analyzer or an external pump, air is aspirated from one nostril. The contralateral nostril is left open, and the subject either holds his breath or breathes through the mouth. Thereby, air is forced from one side of the nose to the other via the nasopharynx. To avoid contamination with lower airway NO, the subject can be asked to exhale orally against a resistance in order to close the soft palate (Kimberly *et al.*, 1996; Silkoff *et al.*, 1997). Another suggested method to measure nasal NO is to exhale through the nose after a full vital capacity inhalation. The exhalation should be made at a constant flow rate. Following this procedure the subject then exhales through the mouth at the same flow rate after a full vital capacity inhalation, and the NO values from oral exhalation is subtracted from the ones measured during nasal exhalation (Palm *et al.*, 2000). As NO is continuously released into the nasal airways, the concentration will be dependent on the flow rate by which the sample is aspirated (Lundberg *et al.*, 1996c). Thus, nasal NO concentrations are higher at lower flow rates. It may therefore be preferable to express nasal NO as the output per time unit (e.g., nl/min), which has been shown to be relatively independent of flow rate (Dubois *et al.*, 1998).

The optimal measurement technique for nasal NO is yet to be determined. A reliable and standardized method will allow for better comparisons of results between different laboratories. Indeed, consensus meetings have been arranged to standardize nasal NO measurements, and recommendations for suitable sampling techniques are available (Kharitonov *et al.*, 1997a; ATS Taskforce, 1999).

FACTORS INFLUENCING NASAL NO

Physiological Factors Nasal NO has been measured in healthy subjects at different ages ranging from zero to 70 years of age, and it has been found that NO is already present at birth (Lundberg *et al.*, 1995a; Schedin *et al.*, 1996). Schedin *et al.* (1996) also found significant nasal NO levels in newborns, including those delivered by cesarian section (Schedin *et al.*, 1996). There is no obvious decline in nasal levels on aging, although large population studies are yet to be performed. There is no evidence of sex differences in nasal NO; however, variations in relation to the menstrual cycle have not yet been studied. NO output in the nasal airways is acutely decreased by physical exercise (Lundberg *et al.*, 1996d; Imada *et al.*, 1996; Phillips *et al.*, 1996; Yasuda *et al.*, 1997). This decrease cannot be explained merely by dilution of nasal air due to changes in nasal cavity volume or increased ventilation. Instead, these changes have been attributed to a reduction in mucosal blood flow of the nasal

airways with a concomitant decrease in substrate supply to the high-rate producing NOS (Lundberg *et al.*, 1996d).

Effects of Disease In children with Kartagener's syndrome, which is a triad consisting of sinusitis, bronchiectasis, and *situs inversus*, nasal NO levels are extremely low compared to healthy age-matched controls (Lundberg *et al.*, 1994a). Also in patients with cystic fibrosis nasal NO is very low (Lundberg *et al.*, 1996a; Balfour-Lynn *et al.*, 1996; Dotsch *et al.*, 1996) (see Fig. 2). Baraldi *et al.* (1997) measured nasal NO in a group of children with acute sinusitis and found low nasal NO. In these patients nasal NO increased when the patients improved following treatment with antibiotics. Also chronic sinusitis is associated with a more than 50% reduction in nasal NO (Lindberg *et al.*, 1997a). In general, the previously mentioned studies indicate that nasal NO is lower in subjects with sinus disorders. It has not been established if the low nasal values in patients with sinus disorders is a result of altered passage of NO gas from the sinuses to the nasal cavity or if the actual production of NO in the sinuses is decreased in these patients. However, in the case of Kartagener's syndrome it is likely that there is a primary defect in NO synthesis in the nasal airways since NO levels are extremely low despite open paranasal sinuses as assessed by a computed tomography scan (Arnal *et al.*, 1999).

Whether or not nasal NO is altered in patients with rhinitis of different etiology has not been fully established. Some groups have reported higher nasal NO in patients with allergic rhinitis (Martin *et al.*, 1996; Kharitonov *et al.*, 1997b; Arnal *et al.*, 1997). In one study nasal NO decreased following treatment with nasal topical steroids (Kharitonov *et al.*, 1997b). Kirsten *et al.* (1997) reported increased nasal NO in human subjects after nasal challenge with endotoxin-containing swine confinement dust. In contrast, no alterations in nasal NO were found in a group of children with perennial rhinitis (Lundberg *et al.*, 1996a). The reasons for the discrepancies between the studies are not clear. One might speculate that iNOS is upregulated in the nose during rhinitis (Furukawa *et al.*, 1996; Kawamoto *et al.*, 1998), as is the case in the lower airways in asthma (Hamid *et al.*, 1993). This would explain the higher levels of NO reported in some studies. On the other hand, the swelling of the nasal mucosa during rhinitis might also lead to partial blockage of the sinus ostia, which would result in less passage of sinus NO into the nasal cavity where NO is measured.

Ferguson and Eccles (1997) measured nasal NO in patients with a common cold but failed to see any differences in NO compared to healthy controls. In another study on experimental human influenza nasal NO levels decreased slightly during the symptomatic period (Murphy *et al.*, 1998).

Effects of Drugs Early reports on the effect of topical glucocorticoids showed no effect of these drugs on nasal NO in healthy individuals (Lundberg *et al.*, 1994a). In fact, not even systemic steroids in high doses seemed to alter normal nasal NO levels (Lundberg *et al.*, 1996b). Systemic

antibiotic treatment does not seem to affect nasal NO (Lundberg *et al.*, 1994a). Moreover, newborn babies delivered by cesarian section had high nasal NO levels as mentioned earlier (Schedin *et al.*, 1996). Therefore, nasal NO release seems to be independent of bacteria normally present in the nasopharynx.

Topical nasal decongestants such as oxymetazoline have been shown to decrease nasal NO (Holden *et al.*, 1999; Rinder *et al.*, 1996). The reason for this is not clear, but it has been suggested that the decrease in nasal/sinus blood flow induced by these drugs leads to a reduction of substrate supply to the high-producing iNOS in the upper airways (Rinder *et al.*, 1996). Indeed, substrate supply seems to be of importance for nasal/sinus NO release, because i.v. administration of L-arginine resulted in an increase in nasal NO levels (Lundberg *et al.*, 1996b). However, Rinder *et al.* (1996) looked at the effects of histamine and capsaicin on nasal NO but found no effects of these drugs.

The NO synthase inhibitor L-NAME has only minor effects on nasal NO when administered locally in the nose (Lundberg *et al.*, 1995a; Rinder *et al.*, 1996). In contrast, Albert *et al.* (1997) found a substantial decrease in nasal NO following i.v. administration of *N*^G-monomethyl-L-arginine (L-NMMA), another NOS inhibitor. Nasal NO has been reported to be lower in cigarette smokers (Gerlach *et al.*, 1994; Robbins *et al.*, 1997), but increases 1 week after smoking cessation (Robbins *et al.*, 1997).

ANIMAL MODELS

Schedin *et al.* (1997) have measured upper airway NO in a large number of species and found high levels only in primates and in elephants. Lewandowski *et al.* (1998) measured nasal NO in baboons and found only low levels. Because of the large variation in nasal NO output between different species caution should be taken when comparing data from animal models with results from studies in humans.

BIOLOGICAL EFFECTS OF NASAL NO

Although the exact role of nasal NO is far from clear, it is reasonable to believe that this pluripotent gas is involved in a variety of physiological as well as pathophysiological events in the airways.

Host Defense Among the various biological properties of NO are its effects on the growth of various pathogens including bacteria, fungi, and virus (Xie and Nathan, 1994). NO produced by white blood cells is thought to be important in the killing of certain microorganisms by these cells. Furthermore, some bacteria are sensitive to authentic NO gas in concentrations as low as 100 ppb (Mancinelli and McKay, 1983). The fact that local NO concentrations in the nasal airways may be several hundred times higher than this supports the notion that NO is involved in local host defense in the upper airways. Local concentrations in the paranasal sinuses can reach 30,000 ppb, which may help to keep the

sinuses sterile under normal conditions (Lundberg *et al.*, 1995a). The very low nasal NO in patients with Kartagener's syndrome or cystic fibrosis (Lundberg *et al.*, 1996a) may contribute to the increased susceptibility to airway infections in these patients. If this is correct, a stimulation of endogenous NO production could increase the resistance to airway infections in patients with low nasal NO as suggested earlier (Lundberg *et al.*, 1994a). It is not clear if NO itself acts directly on microorganisms or if it combines with other components to yield other reactive nitrogen intermediates that are toxic (Xie and Nathan, 1994).

Besides acting directly on microorganisms, NO may also contribute to local host defense by stimulating ciliary motility (Jain *et al.*, 1993). A study by Runer *et al.* (1998) in humans shows that application of an NO donor agent in the nasal mucosa indeed did cause an increase in ciliary beat frequency. Furthermore, the same group has shown that low levels of nasal NO correlate to impaired mucociliary function in the human upper airways (Lundberg *et al.*, 1997b). Interestingly, patients with primary ciliary dyskinesia have extremely low levels of nasal NO as mentioned earlier (Lundberg *et al.*, 1994a), and administration of L-arginine may increase both NO levels and improve ciliary function (Loukides *et al.*, 1998).

Nasal NO as an Airborne Messenger The effects of inhaled exogenous NO are currently being investigated in large clinical trials in treatment of patients with pulmonary hypertension and/or adult respiratory distress syndrome, and inhaled NO has presently found its clinical use in newborn children with persistent pulmonary hypertension (Davidson *et al.*, 1998). Several investigators have found clear effects on arterial oxygenation and pulmonary arterial pressure using concentrations of inhaled NO as low as 10–100 ppb (Puybasset *et al.*, 1994; Gerlach *et al.*, 1993). Interestingly, during normal breathing endogenous NO is inhaled at concentrations (~100 ppb) which are known to have vasodilating effects in the pulmonary circulation (Lundberg *et al.*, 1994a; Gerlach *et al.*, 1994). Nasal breathing reduces pulmonary vascular resistance and improves arterial oxygenation compared to oral breathing in subjects without lung pathology (Settergren *et al.*, 1998; Lundberg *et al.*, 1995b, 1996e). Addition of 100 ppb during oral breathing mimicked the effect of nasal breathing, whereas moistened air during oral breathing had no effect (Lundberg *et al.*, 1996e). Intubated patients are deprived of the natural inhalation of endogenous upper airway NO. Autosupplementation of nasal air to intubated patients treated with a ventilator also improves arterial oxygenation and reduces pulmonary vascular resistance (Lundberg *et al.*, 1995b) (Fig. 3). Moreover, Pinsky and co-workers have shown that hospital pressurized air may contain NO levels similar to those described earlier (6–500 ppb), which may consequently have effects on arterial oxygenation and pulmonary arterial pressure in mechanically ventilated patients (Lee *et al.*, 1997; Pinsky *et al.*, 1997). In another study, nostril widening by a nasal tape, improved arterial oxygenation in

Figure 3 Arterial oxygen tension (PaO_2) in four intubated patients. Air was aspirated (2 liters/min) in 30-min periods from either ambient NO-free air (Ambient air) or from the nostril of the patient (Nasal sampling). The aspirated air was added to the inspiratory flow of the ventilator, and arterial oxygen tension was determined at the end of each sampling period. From Lundberg *et al.* (1995b) with permission.

spontaneously breathing patients, possibly by enhancing ventilation through the nasal airways thereby increasing the delivery of NO from the nasal airways to the lungs (Herulf *et al.*, 1999a).

These results show that NO derived from the upper airways is capable of improving oxygen uptake and reducing pulmonary vascular resistance. It is tempting to speculate that the marked production of NO in the nasal airways has the purpose of modulating lung function in humans. Because NO is produced proximally in the airways, this vasodilating gas will only affect pulmonary vessels in contact with ventilated alveoli, thereby improving V/Q matching. This new physiological principle of NO as an airborne mediator may extend beyond vasodilation. Further studies will reveal if inhalation of endogenous NO will also have antimicrobial effects, upregulate ciliary motility, inhibit platelet aggregation, and downregulate inflammatory mediators in the lungs. If this is true the well-known complications associated with long-term intubation and ventilation, such as ciliary dysfunction and bacterial infections, may partly be explained by the lack of NO due to disruption of the natural low-dose flushing of the airways by self-inhalation of endogenous NO from the upper airways. In that case, a supplementation with physiological levels of NO to intubated patients would be beneficial.

CLINICAL VALUE OF NASAL NO MEASUREMENTS

Measurements of nasal NO are noninvasive and can easily be performed even in small children. The finding of low nasal NO in patients with chronic sinus disorders such as Kartagener's syndrome (Lundberg *et al.*, 1994a) and cystic fibrosis (Lundberg *et al.*, 1996a) are interesting. Nasal NO measurements may be used to facilitate early diagnosis of these two respiratory disorders.

The possible usefulness of nasal NO measurements in the diagnosis and therapeutic monitoring of allergic rhinitis clearly needs to be further evaluated. If nasal NO is a reliable marker of local inflammation, this simple test may be used to monitor patients with rhinitis of different etiology.

The clinical relevance of the fact that intubated patients are deprived of the autoinhalation of NO produced in the nasal airways is not clear. However, when considering the possible beneficial effects of nasal NO on pulmonary function, it is possible that a supplementation with NO at endogenous levels would be of benefit to these patients. One way of achieving this is to collect NO-containing air from the upper airways of the patient and to reintroduce this air to the inspiratory limb of the ventilator (Lundberg *et al.*, 1995b).

In light of the great impact NO has on various physiological as well as pathophysiological events, we now see drugs that effect endogenous NO synthesis emerging as candidates for clinical use. These drugs may either facilitate or decrease NO production, for example, by interfering with the activity or expression of the different forms of NOS. Measurement of nasal NO could be an interesting noninvasive means of monitoring the effects of such drugs in order to optimize the dosage. The nonselective NOS inhibitor L-NMMA is currently being investigated for use in patients with sepsis. Interestingly, this inhibitor, when administered intravenously, leads to a dose-dependent decrease in nasal NO (Albert *et al.*, 1997). Conversely, systemic administration of L-arginine increases nasal NO (Lundberg *et al.*, 1996b).

Lower Airways

MEASUREMENTS OF EXHALED NO

Orally exhaled NO can be measured either during single breath exhalations or during continuous breathing (Kharitonov *et al.*, 1997a). Rapid registration of exhaled NO levels during the course of a single exhalation allows fractioning of a breath into early and late phases. For single breath measurements, a subject takes a deep breath of NO-free air and exhales into a system of appropriate tubing (e.g., Teflon) from which an air fraction is continuously sampled, and NO is measured in the sample (Lundberg *et al.*, 1996c; Kharitonov *et al.*, 1997a; ATS Taskforce, 1999). The velocity of the exhalation will influence the concentration of NO in exhaled air and also the amount excreted from the respiratory tract (Lundberg *et al.*, 1996c; Silkoff *et al.*, 1997). Owing to the flow dependency of NO in exhaled air, it is vital to carefully monitor the exhalation flow rate when measuring NO. One further consideration regarding orally exhaled NO is the possible contamination of NO from the upper airways. It has been suggested that this unwanted addition of NO when one is studying the lower airways may be avoided by applying a positive mouth pressure during exhalation, thereby closing the soft palate (Kimberly *et al.*, 1996; Silkoff *et al.*, 1997). In urban areas, ambient NO levels may sometimes exceed 100 ppb, and in these situations a closed system is preferable, in which NO-free air is inhaled from a reservoir (Alving *et al.*, 1993). Also, the oral cavity is a source of NO which

may affect exhaled NO levels (Duncan *et al.*, 1995; Zetterquist *et al.*, 1999).

NO may also be measured during normal tidal breathing. This method is suitable for continuous measurements of NO over longer periods of time, for example, to study the effect of physical exercise on exhaled NO levels (Lundberg *et al.*, 1996c) and in the intensive care setting. This method has also been suggested when measuring in small children who may have problems in complying with single exhalation maneuvers. As with the single-breath measurements, one must also bear in mind the influence of flow rate on NO concentrations when using this method. As with nasal NO measurements, recommendations for suitable sampling techniques have been proposed (Kharitonov *et al.*, 1997a; ATS Taskforce, 1999).

NOS ISOFORMS IN THE AIRWAYS

It is likely that most of the NO found in exhaled air is endogenously produced by NOSs present in airway mucosal cells. In a number of studies, inhaled NOS inhibitors have markedly reduced airway excretion of NO (Gustafsson *et al.*, 1991; Lundberg *et al.*, 1995a; Yates *et al.*, 1995). However, a bacterial contribution to luminal NO cannot be entirely excluded, because some strains of bacteria are known to produce NO from nitrite (Ji and Hollocher, 1989). Furthermore, studies indicate that NO may be chemically formed in the oral cavity by reduction of salivary nitrite at the surface of the tongue (Duncan *et al.*, 1995; Zetterquist *et al.*, 1999).

All three known isoforms of NOS have been identified in human airway mucosa. Endothelial NOS (eNOS) is found in mucosal blood vessels and also in cultured human bronchial epithelium (Shaul *et al.*, 1994). Neuronal NOS (nNOS) has been identified in bronchial epithelial cells (Asano *et al.*, 1994) as well as in certain mucosal nerves. iNOS may be expressed in bronchial epithelial cells, for example, during inflammation (Hamid *et al.*, 1993) or *in vitro* after stimulation with certain cytokines (Asano *et al.*, 1994). However, there has been confusion in the literature as to whether this NOS isoform is also present in healthy bronchial epithelium. Hamid *et al.* (1993) and Asano *et al.* (1994) found no evidence of iNOS expression in healthy bronchial epithelium, whereas Guo *et al.* (1995) reported iNOS expression also in bronchial mucosa of healthy subjects. As discussed earlier, however, it seems quite clear that in certain areas of the upper airways iNOS is constitutively expressed (Lundberg *et al.*, 1995a).

Factors Influencing Exhaled NO

Today we know a little about the various physiological and pathological factors that influence levels of NO in exhaled air, although much still remains to be studied. In the following we will discuss some of these factors.

Physiological Factors No studies have shown that body posture has any influence on orally exhaled NO levels. In healthy men and children, intraindividual changes in orally

exhaled NO over time seem to be minor, provided that the measurements are performed in the same way (Lundberg *et al.*, 1994a, 1996c). In menstruating women variations of exhaled NO in synchrony with the menstrual cycle have been reported (Kharitonov *et al.*, 1994). Thus, exhaled NO peaked at midcycle during ovulation, whereas it dropped during menstruations. Exhaled NO levels have been reported to remain fairly constant during the course of a normal pregnancy (Grunewald *et al.*, 1998; Morris *et al.*, 1995).

Several groups have investigated whether orally exhaled NO levels are affected by physical exercise (Trolin *et al.*, 1994; Iwamoto *et al.*, 1994; Persson *et al.*, 1993). The results are similar; absolute concentrations of exhaled NO decrease during exercise, but since the ventilation increases greatly, the calculated amounts of excreted NO are increased.

The amount of NO exhaled by cigarette smokers has been observed to be lower than normal (Gerlach *et al.*, 1994; Persson *et al.*, 1993). The reason for this is not clear, but it could be due to a downregulation of endogenous NO synthesis because of the high NO content in cigarette smoke (Norman and Keith, 1965), damage to NO-producing cells by toxic agents in smoke, or increased trapping of NO in the airway fluid line. The presence of NO in cigarette smoke also explains its vasodilatory effects on the pulmonary and bronchial circulation (Alving *et al.*, 1993). Because basal NO release from the lower airways is very low, as discussed earlier, it is likely that this downregulation occurs in the upper parts of the airways. Indeed, Gerlach *et al.* (1994) reported lower nasopharyngeal NO levels in smokers than in nonsmokers.

It has been shown that intake of nitrate, which is present, for example, in green leafy vegetables, increases NO in orally exhaled air significantly (Zetterquist *et al.*, 1999). This is probably due to increased production of NO in the oral cavity. Nitrate is actively secreted into the saliva (Spiegelhalder *et al.*, 1976), and reduction of salivary nitrate/nitrite by bacteria on the base of the tongue leads to NO generation. Zetterquist *et al.* (1999) could reduce this increment in exhaled NO after nitrate with an antibacterial mouthwash.

Asthma and Exhaled NO Inflammation in general has been reported to be associated with enhanced production of NO, and NO has been implicated in the pathogenesis of certain inflammatory diseases (Lundberg *et al.*, 1997a; Nussler and Billiar, 1993). In 1993, Alving *et al.* reported increased NO levels in orally exhaled air of asthmatics. These findings have since been confirmed by numerous research groups (for review, see Lundberg *et al.*, 1996c; Kharitonov *et al.*, 1997a; ATS Taskforce, 1999). Hamid *et al.* (1993) reported expression of iNOS in asthmatic bronchial epithelium but not in control bronchial tissue from healthy subjects. This may be one explanation for the elevation of the orally exhaled NO levels in asthmatic patients. However, other sources such as macrophages, mast cells, nerve cells, or other NO-generating cells in the inflamed mucosa cannot be excluded. Glucocorticoids are known to inhibit the expression of iNOS (Nathan and Xie, 1994). Therefore, one would expect that exhaled

NO levels would decrease in patients on treatment with such drugs. Indeed, treatment with inhaled steroids leads to a reduction in exhaled NO in asthmatics (Yates *et al.*, 1995). In asthmatic children a dose dependency has been observed; those treated with no or low to moderate doses of topical steroids showed increased exhaled NO, whereas those treated with the highest doses of steroids showed exhaled NO levels that did not differ from controls (Lundberg *et al.*, 1996a). Numerous studies have shown a dose-dependent reduction in exhaled NO with steroid treatment and correlation between other markers of airway inflammation such as eosinophilia in induced sputum and bronchoalveolar lavage fluid (Jatakanon *et al.*, 1998; Piacentini *et al.*, 1999). Also, newer anti-inflammatory agents used in asthma such as leukotriene inhibitors may reduce exhaled NO levels (Bisgaard *et al.*, 1999), whereas inhaled B agonists have only minor effects (Yates *et al.*, 1997; Fuglsang *et al.*, 1998) (Table I). Kharitonov *et al.* (1995a) reported further elevation of exhaled NO during the late-phase reaction of asthmatics. Measurements were made after antigen challenge, and only dual responders showed elevated exhaled NO levels. This indicates that the late-phase reaction increase in NO levels is due to an inflammation-driven increase in iNOS expression.

Altogether, many studies on exhaled NO in asthmatics have now been performed, and it is likely that the expression of an iNOS in asthmatic airways is responsible for the elevation in exhaled NO levels seen in these patients. Asthma therapy today is very much focused on treatment of the underlying inflammatory disease, and there is a great need for an objective marker of airway inflammation. It is tempting to speculate on the possible usefulness of NO in exhaled air as a marker of airway inflammation; these measurements are easy to perform, are noninvasive and objective, and rapidly provide information about a local process. However, more studies are needed to investigate the potential of this method in the diagnosis and monitoring of airway inflammation.

Other Diseases of the Respiratory Tract Asthma is not the only airway disease associated with alterations in exhaled NO. Alving *et al.* (1993a) reported transient elevations of orally exhaled NO in subjects with lower respiratory tract infection, and Kharitonov *et al.* (1995b) reported increased NO levels during the symptomatic period in subjects with upper airway infection. Increased NO levels have also been reported in patients with bronchiectasis (Kharitonov *et al.*, 1995c). In patients with chronic obstructive pulmonary dis-

ease, exhaled NO is increased during periods of exacerbation (Agusti *et al.*, 1999; Corradi *et al.*, 1999; Clini *et al.*, 1998). In lung transplant recipients exhaled NO levels have been reported to increase with signs of pulmonary graft dysfunction (Marczin *et al.*, 1997a; Silkoff *et al.*, 1998). Hence, both inflammation and infection in the airways may be associated with enhanced airway production of NO. This is not surprising because the known factors that induce expression of iNOS (e.g., certain proinflammatory cytokines and bacterial products) may be present in increased amounts in inflamed/infected tissues.

Drugs Only little is known about the effects of drugs on NO excretion in the airways. However, some agents that are known to interfere with airway NO release will be discussed later.

Glucocorticoids have been mentioned earlier; these agents depress already increased exhaled NO levels in, for example, asthmatics. However, steroids do not influence basal exhaled NO levels in healthy individuals (Lundberg *et al.*, 1994a, 1996b). Yates *et al.* (1995) reported decreased orally exhaled NO levels in controls and in asthmatics following oral inhalation of an NOS inhibitor. In addition, the inhaled selective iNOS inhibitor aminoguanidine reduces exhaled NO in asthmatics (Yates *et al.*, 1996). L-Arginine, the substrate for enzymatic NO synthesis, has been shown to increase exhaled NO in a dose-dependent matter when taken orally (Kharitonov *et al.*, 1995d) or infused intravenously (Lundberg *et al.*, 1996b).

Persson *et al.* (1994a) reported decreased orally exhaled NO levels following ingestion of ethanol. Nitrovasodilators such as nitroglycerine act through the release of NO, and increased exhaled NO levels have been observed in experimental animals following i.v. administration of this drug (Persson *et al.*, 1994b). However, in humans data are conflicting as to whether NO-donating drugs may affect exhaled NO levels (Marczin *et al.*, 1997b; Dirnberger *et al.*, 1998).

Nitric Oxide and Airway Inflammation

NO produced by iNOS has also been implicated in the pathogenesis of inflammation (Nussler and Billiar, 1993), and NO synthesis is clearly enhanced locally at sites of inflammation (Lundberg *et al.*, 1997a), although the role of NO in the pathogenesis of inflammation is far from settled. Some studies indicate a harmful role of NO during inflammation, whereas others indicate the opposite. Possible proinflammatory actions of NO include activation of enzymes such as cyclooxygenase (Salvemini *et al.*, 1993) or metalloproteases (Murell *et al.*, 1995). Moreover, peroxynitrite, formed from the reaction of NO with superoxide, can exert toxic effects on tissues (Sato *et al.*, 1998; Beckman *et al.*, 1990). NO has also been implicated in the pathogenesis of pertussis, as NOS inhibitors dramatically attenuated the epithelial damaging effects of a cytotoxin that is released by *Bordetella pertussis* (Heiss *et al.*, 1994). The possible harmful effects of NO have been attributed to the large amounts

Table I Effects of Some Antiasthmatic Drugs on Exhaled NO in Asthmatics

Drug	Administration	Exhaled NO
Corticosteroids	Topical, intravenous	Decrease
β_2 adrenoceptor agonists	Topical	Minor increase
Leukotriene antagonists	Perorally	Decrease

of this gas produced by iNOS during inflammation. However, the finding of a constantly expressed iNOS in the nasal airways (Lundberg *et al.*, 1995a) complicates this picture, because it clearly demonstrates that the sole expression of iNOS and the subsequent large production of NO is not associated with tissue damage. On the contrary, iNOS in the upper airways may serve important protective functions, as discussed earlier. It has also been suggested that upregulation of NO synthesis in asthma serves to counterbalance bronchoconstrictor stimuli (Gaston *et al.*, 1994).

Gastrointestinal Tract

Stomach

NONENZYMATIC INTRAGASTRIC NO PRODUCTION

Human saliva contains both nitrate and nitrite (Tannenbaum *et al.*, 1976). Dietary nitrate, derived mainly from green leafy vegetables, is absorbed in the gastrointestinal tract. For largely unknown reasons, up to 25% of circulating nitrate is actively taken up by the salivary glands and secreted in saliva (Spiegelhalter *et al.*, 1976). Bacteria in the oral cavity reduce parts of the salivary nitrate to nitrite (Bartsch *et al.*, 1988). Further reduction of nitrite to nitric oxide and other nitrogen oxides is a well-known chemical reaction that occurs in acidic solutions. It was shown that NO is formed in the stomach following reduction of salivary-derived nitrite (Lundberg *et al.*, 1994b; Benjamin *et al.*,

1994; McKnight *et al.*, 1997). Intra gastric NO production from nitrite is dependent on a reducing/acidic environment, as stated earlier. Indeed, when acid production was blocked in the stomach with large doses of the proton-pump inhibitor omeprazole, NO production was almost completely abolished (Lundberg *et al.*, 1994b). Furthermore, *in vitro* studies using nitrite solutions at different pH showed a clear correlation between NO release and pH (Lundberg *et al.*, 1994b). The daily saliva production may exceed 1 liter, which ensures a continuous NO production in the acidic stomach. McKnight *et al.* (1997) reported mean values of about 14 ppm in the fasting stomach, and these values rose to about 90 ppm following ingestion of nitrate. In this and an earlier study (Lundberg *et al.*, 1994b), no attempts were made to calculate the actual production rate of NO in the stomach. Such estimations will be of help when further evaluating the possible biological role of NO in the stomach. Intra gastric NO production is already initiated in the oral cavity by the reduction of nitrate to nitrite. Thus, commensal bacteria inhabiting the oral cavity produce the necessary substrate for the NO production that takes place in the stomach when nitrate-containing saliva is swallowed. This seems to be yet another example of symbiosis between organisms in nature.

The accumulation of nitrate in saliva seems to be part of a recycling of NO produced either nonenzymatically or by NOSs from L-arginine (Fig. 4). NO produced from L-arginine, for example, in endothelial cells, is converted to nitrate following reaction with hemoglobin in the blood (Moncada *et al.*, 1991). In fasting humans the L-arginine–NO pathway

Figure 4 Intra-gastric generation of nitric oxide from nitrate and nitrite. (A) Dietary sources of nitrate and nitrite include green leafy vegetables and processed meat. (B) Nitrate is partly reduced to nitrite by bacteria in the oral cavity. (C) Nitric oxide and other nitrogen oxides are formed from nitrite in swallowed saliva in the acidic stomach. (D) Remaining nitrate is absorbed in the gastrointestinal tract. (E) Plasma nitrate originates from dietary sources as well as from oxidation of endogenously produced NO from the L-arginine/NOS pathway. (F) About 25% of plasma nitrate is actively taken up by the salivary glands and excreted in saliva. (G) A large portion of circulating nitrate is excreted in urine.

constitutes a major source of nitrate/nitrite levels in plasma (Rhodes *et al.*, 1995), and net nitrate synthesis ranges between 0.1 and 2 mmoles per day (Green *et al.*, 1981). In addition, similar amounts of nitrate are normally ingested (Forman *et al.*, 1985). Nitrate is taken up from the plasma by the salivary glands, and parts of it may eventually turn up as NO again in the stomach as described earlier. Because the substrate for intragastric NO production is derived not only from dietary sources, this production may occur even when intake of nitrate/nitrite is low.

POSSIBLE ROLE OF NO IN THE STOMACH

NO is a tiny lipophilic molecule that easily travels across biological membranes. At a concentration of 20–100 ppb, NO gas has been shown to cause vasodilation (Lundberg *et al.*, 1995b) and to inhibit the growth of certain bacteria (Mancinelli and McKay, 1985). Because intragastric NO levels are up to 4000 times higher (Lundberg *et al.*, 1994b; McKnight *et al.*, 1997), it is likely that locally produced NO has biological effects in the stomach. Indeed, it was shown that nitrite, when acidified, killed various gut pathogens much more effectively than did acid alone (Benjamin *et al.*, 1994). Interestingly, *Helicobacter pylori*, the bacterium involved in the pathogenesis of ulcer disease, is also sensitive to acidified nitrite (Dykhuizen *et al.*, 1998). It should be kept in mind that other nitrogen intermediates such as nitrogen dioxide (NO₂) and nitrous acid (HNO₂) are also produced from acidified nitrite, and these compounds may have bacteriostatic effects as well (Kaplan *et al.*, 1996; Kono *et al.*, 1994). Thus, NO may not account for all effects observed in the cited studies.

Intragastric NO may also be involved in regulation of mucosal blood flow and mucus formation. Indeed, it has been shown that instillation of an NO donor agent into the gastric lumen produces an increase in mucus formation that is inhibited by coadministration of oxyhemoglobin (an NO scavenger), suggesting that the effect was mediated by local NO release (Brown *et al.*, 1992). Furthermore, topical administration of nitrite to the gastric mucosa increases mucosal blood volume (Kitagawa *et al.*, 1990). An adequate blood flow is essential if the gastric mucosa is to withstand the challenge of both exogenous and endogenous aggressors, and local ischemia is an important mechanism underlying various forms of gastric damage (Whittle, 1993). As mentioned earlier, intragastric NO production is strongly pH-dependent, with more NO being produced at lower pH (Lundberg *et al.*, 1994b). Thus, NO formation in the stomach is enhanced in response to challenge with acid. In this way NO may help to counteract potential acid-induced damage by increasing superficial mucosal blood flow.

There has been concern that dietary nitrates/nitrites may have deleterious effects (Tannenbaum *et al.*, 1974; Bartsch *et al.*, 1988). This concern is not primarily related to the nitrate ion but to the fact that nitrate-reducing bacteria in the oral cavity reduce nitrate to nitrite. In the stomach, nitrogen oxides formed from nitrite may react with amines, resulting in the formation of harmful N-nitroso compounds (NOCs), a

versatile class of carcinogens in animals (Tannebaum *et al.*, 1974; Bartsch *et al.*, 1988). However, results from epidemiological studies in humans are conflicting. In fact, a study by Forman *et al.* (1988) showed a negative correlation between salivary nitrate/nitrite concentrations and the risk of developing gastric cancer. The reason for this was not clear, but it was speculated that the high ascorbate content in nitrate-rich vegetables could have a protecting effect. Indeed, epidemiological studies have clearly shown that compounds known to inhibit NOC formation also have a protective effect against cancers, in particular gastric cancer (Bartsch *et al.*, 1988). Interestingly, a great variety of agents (including vitamin C) that inhibit NOC formation do so by reducing the nitrosating agent to NO, which is not a nitrosating agent (Bartsch *et al.*, 1988; Licht *et al.* 1988).

ORAL CAVITY

A similar mechanism of NO production from acidified nitrite has also been described in the oral cavity (Duncan *et al.*, 1995; Zetterquist *et al.*, 1999), even though less NO is being produced during the day, most likely owing to a higher pH in the mouth compared to the stomach. Nevertheless, it has also been suggested that NO may play a role in host defense in the mouth (Duncan *et al.*, 1995). NO production from nitrite in the oral cavity may interfere with measurements of exhaled NO (Zetterquist *et al.*, 1999). This is further discussed earlier in the airway section.

Intestines

Nitric oxide is present in the lumen of the small and large intestines in humans (Lundberg *et al.*, 1994c; Everts *et al.*, 1999). The levels in healthy individuals vary between 30 and 200 ppb, as measured with chemiluminescence during colonoscopy (Lundberg *et al.*, 1994c). The exact origin of the luminal NO in healthy subjects is not known. NO may be constitutively generated in the mucosa, submucosa, and muscle from neural, endothelial, and epithelial cells (Salzmann, 1995; Whittle, 1994). It is, however, likely that the luminal NO is derived from the nearby epithelium, in which both constitutive and inducible NOS have been found (Salzmann, 1995; Whittle, 1994). An additional source of nitrogen oxides from the gastrointestinal tract arises from the production of NO by luminal anaerobic microorganisms that use nitrate and nitrite for their respiration (Whittle, 1994). However, luminal NO, measured in the rectum in humans, is unaltered with or without the presence of fecal matter (Herulf *et al.*, 1998), indicating only a minor contribution of NO from bacterial reduction of nitrate/nitrite. NO may play a role in different physiological events in the gastrointestinal tract. It participates in regulation of perfusion to match the demand required for digestion, tissue oxygenation, and mucosal integrity. The release of NO from the nonadrenergic–noncholinergic (NANC) enteric nervous system plays a critical role in coordination of bowel motility (Whittle, 1994). It has also been suggested that NO has a role in fluid and electrolyte transport in the gut (Salzmann, 1995).

INFLAMMATION

In inflammatory bowel diseases (IBD) there is an increased production of NO. This was first described by Middleton *et al.* in 1993, who reported increased citrulline relative to other amino acids as indirect evidence of increased NO synthesis in rectal biopsy specimens from patients with active ulcerative colitis. Later the same year, Boughton-Smith *et al.* (1993) could demonstrate an eight-fold increase in NOS activity in mucosal specimens from inflamed areas taken from six patients with ulcerative colitis. Singer *et al.* (1996) examined the cellular distribution of iNOS in normal bowel, ulcerative colitis, and Crohn's disease using immunoperoxidase staining with a monospecific human iNOS antibody. Intense focal iNOS labeling has been localized to inflamed colonic epithelium in ulcerative colitis and Crohn's disease but negative in controls (Singer *et al.*, 1996; Kimura *et al.*, 1998; Ikeda *et al.*, 1997). Also, in celiac disease increased iNOS activity has been described (Beckett *et al.*, 1998). However, in contrast to the localization of increased iNOS to the epithelial cells in ulcerative colitis, iNOS activity in celiac disease was primarily increased in the lamina propria (Beckett *et al.*, 1998). Forte *et al.* (1999) reported increased urinary output of the isotope ^{15}N in patients with acute infective gastroenteritis on administration of L- ^{15}N arginine indicating an increased activity of the L-arginine–NO pathway in this disease. In 1994 Lundberg *et al.* reported results from analysis of aspirated luminal gas obtained during colonoscopy in patients with ulcerative colitis (Lundberg *et al.*, 1994c). The gas was obtained from different parts of the colon using a thin catheter and a syringe, and it was subsequently injected into a chemiluminescence analyzer. Six patients with active ulcerative colitis and 12 controls were examined; luminal NO concentrations were more than 100-fold higher in gas samples from patients than in gas from controls, and there was no overlap between the groups (Fig. 5). Also, in Crohn's disease of the colon, luminal NO levels are very high (Lundberg *et al.*, 1995c). The same group has developed a minimally invasive technique

to measure luminal NO. In this procedure, a balloon-tipped catheter is inserted in the rectum of humans, and then the balloon is inflated with NO-free air, after which luminal NO is allowed to diffuse into the balloon. With this technique, patients with active ulcerative colitis and active Crohn's disease had values 10- to 100-fold higher than did healthy controls or patients with inactive disease (Herulf *et al.*, 1998) (Fig. 5). As mentioned earlier, the presence of intestinal fecal matter did not lead to higher values in that study. Also, in two other chronic inflammatory bowel diseases, collagenous and lymphocytic colitis, luminal NO levels are greatly increased (Lundberg *et al.*, 1997b) (Fig. 5). It was also shown that rectal NO levels are markedly increased in acute infective gastroenteritis (Herulf *et al.*, 1999b). Everts *et al.* (1999) reported elevated luminal NO in the small intestine in patients with untreated celiac disease. We measured rectal NO in patients with treated celiac disease after local challenge with gluten in the rectum (E. Weitzberg and J. O. N. Lundberg, 2000, unpublished observation). NO increased dramatically 24 hours after challenge in about 60% of the patients, whereas no response was seen in the rest of the patients. The reason for this discrepancy is presently not known.

The role of NO in inflammatory bowel diseases is far from settled. As discussed earlier, NO may have potential harmful as well as beneficial effects. There are conflicting data in the literature when using NOS inhibitors (Perner and Rask-Madsen, 1998). McCafferty *et al.* (1997) have shown that mice lacking the iNOS gene develop a much more severe inflammation compared to wild-type controls, indicating a protective role of iNOS in bowel inflammation.

Urinary Tract

NO MEASUREMENTS IN THE BLADDER

Unlike the airways and the intestines, the urinary bladder is normally not an air/gas-containing organ. To measure luminal NO in the bladder, a method has been used in which

Figure 5 Luminal NO levels in patients with various intestinal inflammatory disorders compared to healthy controls. Gas was sampled from the colon or rectum. Data from Lundberg *et al.* (1994c, 1997b) and Herulf *et al.* (1998, 1999b).

NO-free air was introduced into the bladder either during cystoscopy or through a urinary catheter (Lundberg *et al.*, 1996f). After a short incubation period, the air was removed and NO was measured with chemiluminescence technique as described earlier. This method has been further developed using the same technique as for rectal NO measurements. A silicon catheter with an inflatable balloon is introduced into the bladder, and the balloon is inflated with NO-free air, incubated for 5 to 10 min (allowing for NO to diffuse into the balloon), and then measured as described earlier. Using the previously described method, it has been shown that luminal NO in the urinary bladder is increased in patients with cystitis of different etiology (Ehren *et al.*, 1999a). The cellular source of this NO has not been pinpointed.

THE ROLE OF NO

The role of NO in cystitis is not clear. NO or subsequent reaction products may be cytotoxic to host cells when produced in excess as discussed earlier. On the other hand, increased NO production might enhance local host defense mechanisms in the bladder, keeping in mind the well-known bacteriostatic, antiviral, and antitumor properties of this gas. Thus, NOS expression in the urinary bladder mucosa may be induced in response to, for example, bacterial endotoxins. It will be of interest to study if the various pathogens that cause cystitis differ in their capacity to induce mucosal NO synthesis. Local instillation of *Bacillus Calmette-Guérin* (BCG) into the bladder is frequently used in the treatment of superficial recurrent bladder cancer. The mechanism of action is not fully understood, but it is thought to be related to a local inflammatory response involving upregulation of cy-

tokines (Jackson *et al.*, 1995), many of which may promote iNOS expression. Interestingly, patients treated with BCG showed a marked increase in bladder NO production, suggesting that NO may contribute to the antitumor effects of this treatment (Lundberg *et al.*, 1996f). A study by Jansson *et al.* (1998) showed that NO donor agents caused inhibition of bladder tumor cell growth, suggesting an antitumor effect of NO in this model. The same may be true for irradiation therapy in cancer treatment. Thus, bladder concentrations of NO were also greatly increased in patients with irradiation cystitis (Lundberg *et al.*, 1996f).

CLINICAL USE OF BLADDER NO MEASUREMENTS

Lower urinary tract symptoms, for example, urgency, frequency, nocturia, discomfort, and pain, are common among patients referred to the urologist for evaluation. These symptoms may be due to inflammatory or noninflammatory functional disorders, and bladder biopsies are often required to distinguish between the two groups of patients. It is tempting to speculate on the possible usefulness of bladder NO measurements in the diagnosis and monitoring of cystitis. Measurements of NO in the bladder may be a simple way to detect inflammation in the lower urinary tract. A study by Ehren *et al.* (1999b) supports this notion. They looked at bladder NO levels in patients with urgency symptoms due to various noninflammatory disorders and compared the levels with healthy controls and patients with interstitial cystitis, an inflammatory disorder of the bladder with very similar symptoms. Interestingly, only the patients with interstitial cystitis had high NO levels (about 18-fold increase), whereas the other patient groups did not differ from controls. Thus,

Figure 6 Overview describing various locations where airborne NO has been measured in health and disease.

luminal NO seems to be a marker of ongoing inflammation in the bladder. It will be of interest to study whether NO excretion correlates to the severity of inflammation; however, this will require larger groups of patients.

Summary and Conclusion

NO produced in superficial layers of the mucosa may be detected in luminal structures such as the airways, the gastrointestinal tract, and the urinary tract by measuring NO content in gas collected from these hollow organs. This allows for direct on-line measurements of NO generation in humans. Measurements of airborne NO may be a helpful tool in further understanding the role of NO in health and disease.

A large production of NO normally takes place in the nasal airways and in the stomach of healthy individuals. The exact role of this NO is not known but may include host defense actions as well as regulation of blood flow.

Mucosal inflammation in diseases such as asthma, inflammatory bowel disease, and cystitis leads to greatly increased luminal NO levels in the affected organs (Fig. 6). Exhaled NO levels are elevated in asthma and substantial evidence now suggests NO to be a clinically useful noninvasive marker of airway inflammation. NO measurements may be a valuable tool in evaluating effects of anti-inflammatory treatment. Furthermore, we will likely witness new therapies emerging that are focused on pharmacological intervention of endogenous NO production in various diseases. In these situations NO measurements may prove to be helpful.

Nitric Oxide and Persistent Pulmonary Hypertension in the Newborn

Robin H. Steinhorn* and James A. Russell†

**Department of Pediatrics, Northwestern University
Chicago, Illinois*

*†Departments of Physiology and Pediatrics, State University of New York at Buffalo
Buffalo, New York*

THE TRANSITION OF THE PULMONARY CIRCULATION FROM A HIGH RESISTANCE–LOW FLOW CIRCULATION IN THE FETUS TO A LOW RESISTANCE–HIGH FLOW CIRCULATION IN THE NEWBORN IS A COMPLEX PROCESS THAT INVOLVES THE SIMULTANEOUS DOWNREGULATION OF VASOCONSTRICTOR MEDIATORS AND UPREGULATION OF VASODILATORY MEDIATORS SUCH AS NITRIC OXIDE (NO). IN THE VAST MAJORITY OF INFANTS, THIS PROCESS OCCURS SPONTANEOUSLY AND QUICKLY AND DOES NOT REQUIRE ANY INTERVENTION. OCCASIONALLY, HOWEVER, THE TRANSITION MAY BE DIFFICULT OR ABNORMAL, AND REQUIRE PROMPT AND EFFECTIVE RESUSCITATION TO ENSURE A SUCCESSFUL ADAPTATION TO THE EXTRA-UTERINE ENVIRONMENT.

ONE DISEASE THAT LEADS TO COMPLICATIONS DURING TRANSITION IS PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN (PPHN) WHICH IS CHARACTERIZED BY FAILURE OF THE PULMONARY VASCULAR RESISTANCE (PVR) TO DECREASE AFTER BIRTH, RESULTING IN HYPOXIA AND SEVERE DISTRESS. UNDERSTANDING THE PHYSIOLOGY OF THE PULMONARY CIRCULATION DURING THE TRANSITION FROM FETUS TO NEWBORN HAS HELPED NEONATOLOGISTS DEVELOP NEW TECHNIQUES FOR THE MANAGEMENT OF THIS SERIOUS CONDITION ASSOCIATED WITH HIGH MORTALITY AND MORBIDITY. FOR EXAMPLE, BECAUSE INFANTS WITH PPHN EXHIBIT REDUCED NO SYNTHESIS, INHALED NO IS NOW WIDELY USED TO INCREASE PULMONARY BLOOD FLOW AND CORRECT HYPOXIA IN THESE NEONATES. OTHER METHODS TO INCREASE cGMP, SUCH AS INHIBITION OF cGMP SPECIFIC TYPE 5 PHOSPHODIESTERASE ISOFORM (PDE5), EITHER ALONE OR IN COMBINATION WITH NO, ARE BEING INVESTIGATED AS NOVEL THERAPEUTIC MODALITIES FOR TREATING THIS CONDITION. IT IS ANTICIPATED THAT THIS COMBINATION THERAPY WILL DECREASE THE CONCENTRATION OF NO REQUIRED FOR A THERAPEUTIC EFFECT; THUS ATTENUATING POTENTIALLY DELETERIOUS EFFECTS RESULTING FROM THE FREE RADICAL ACTIONS OF NO.

THIS CHAPTER WILL STRESS THE ROLE OF NO IN (1) THE NORMAL FETAL CIRCULATION, (2) THE TRANSITION OF THE CIRCULATION AT BIRTH, AND (3) THE ETIOLOGY AND TREATMENT OF PPHN IN NEWBORNS. IT IS IMPORTANT TO NOTE THAT ALTHOUGH THEY WILL BE DISCUSSED ONLY BRIEFLY, MULTIPLE FACTORS IN ADDITION TO NO CONTRIBUTE TO BOTH THE NORMAL TRANSITION AND THE PATHOPHYSIOLOGY OF PPHN.

The Normal Fetal Circulation

In the adult, the lung is the organ of gas exchange and receives 50% of the combined ventricular output. In contrast, the placenta serves as the organ of gas exchange during fetal life, and as such receives 50% of the combined ventricular output. Because the lung is not required for gas exchange, pulmonary blood flow is low in the fetus (approximately 10% of the combined ventricular output by term) and PVR is high (Rudolph and Heymann, 1970). This unique physiological state allows adequate pulmonary blood flow for lung growth and development, yet permits venous blood to be shunted across the ductus arteriosus and the foramen ovale so that it can be directed to the placenta for gas exchange (Fig. 1A). Total systemic vascular resistance is low, mainly due to the low-resistance placental circulation.

Structure of Fetal Pulmonary Vessels

The morphologic development of the pulmonary vasculature affects the physiological changes that occur in the perinatal period. In the fetus, small pulmonary arteries have cuboidal endothelium and a thicker muscular coat relative to the external diameter than do similar arteries in the adult. This muscularity is believed to be at least partially responsible for the increased vasoreactivity and high PVR in the fetus, particularly near term. In fetal lungs, the medial smooth muscle coat is most prominent in the fifth and sixth generation arteries (Reid, 1986). In more peripheral vessels,

there is only partial muscularization, and in precapillary arterioles the muscular layer disappears altogether.

During fetal growth in lambs, the number of small pulmonary arteries increases, both in absolute terms and per unit volume of the lung. In the last trimester in fetal lambs, the number of small blood vessels in the lungs increases 40-fold while the wet weight of the lungs increases fourfold. Thus, the number of small blood vessels per unit of lung increases 10-fold, a process which prepares the lungs to accept the 10-fold increase in blood per unit of lung that occurs at birth.

Mediators of High Pulmonary Vascular Tone

Despite the large increase in the cross-sectional area of the pulmonary circulation, PVR remains high in the near-term fetus. Mechanical factors such as absence of an air-liquid interface, compression of the small pulmonary artery (PA) by the fluid filled alveolar space, and lack of rhythmic distention contribute to the maintenance of high resting tone in the fetal lung. However, active vasoconstriction to the low oxygen tension of the normal fetus (17 to 20 mmHg) is a primary mechanism responsible for maintaining high pulmonary vascular resistance during fetal life.

Hypoxic pulmonary vasoconstriction develops over the period of gestation when the cross-sectional area of the vascular bed is increasing rapidly. Increasing or decreasing oxygen tension in the fetal lamb early in the third trimester (70% gestation) does not affect pulmonary vascular resistance (Fig. 2). In contrast, in the near-term fetal lamb, decreasing

Figure 1 The circulations of the (A) normal fetus, (B) the normal newborn, and (C) the newborn with persistent pulmonary hypertension of the newborn. The whiter the vessels, the higher is the saturation of hemoglobin with oxygen. PA, pulmonary artery; FO, foramen ovale; DA, ductus arteriosus; AO, aorta; UA, umbilical artery; UV, umbilical vein; IV, inferior vena cava. From Morin III, F. C., and Stenmark, K. R. (1995). Persistent pulmonary hypertension of the newborn. *American Journal of Respiratory and Critical Care Medicine* 151, 2010–2032. Official Journal of the American Thoracic Society © American Lung Association.

Figure 2 Effect of hyperbaric oxygen on pulmonary blood flow in early third trimester fetal lambs (open circles) and near-term fetal lambs (closed circles). From Morin and Egan (1992), with permission.

oxygen tension doubles PVR, and increasing oxygen tension markedly decreases PVR and increases pulmonary blood flow to normal newborn levels (Morin III and Egan, 1992). Inhibition (closure) of potassium channels in pulmonary vascular smooth muscle cells is a key event that links hypoxia to pulmonary vasoconstriction (Weir and Archer, 1995). Closure of potassium channels in response to hypoxia causes membrane depolarization and subsequent activation of voltage-gated calcium channels, leading to calcium influx and sustained contraction. Precisely which potassium channels are involved in maintaining vasoconstriction to hypoxia is controversial.

Role of Nitric Oxide

DISTRIBUTION OF NOS WITHIN THE FETAL LUNG

In the 1990s, nitric oxide became the agent most extensively studied in the perinatal pulmonary circulation. All three known nitric oxide synthase (NOS) isoforms, neuronal NOS (nNOS or NOS I), inducible NOS (iNOS or NOS II), and endothelial NOS (eNOS or NOS III), are developmentally regulated and differentially distributed in pulmonary vessels and airways of fetal lungs (Loesch and Burnstock, 1996; North *et al.*, 1994a; Sherman *et al.*, 1999; Xue *et al.*, 1996). Neuronal NOS and iNOS are found in the soluble fraction of cells, whereas eNOS is localized to the particulate fraction, primarily in the caveolar membrane fractions isolated from endothelial cell plasma membrane (Shaul *et al.*, 1996). Localization to this microdomain is likely to optimize eNOS activation and the extracellular release of NO.

In pulmonary vessels, eNOS is localized specifically to the endothelium, whereas iNOS and nNOS are found in both endothelial and smooth muscle cells (Sherman *et al.*, 1999; Tzao *et al.*, 1999). Immunostaining for endothelial cell

eNOS in the ovine fetus decreases from large to small pulmonary arteries, whereas staining for nNOS, although abundant, is observed only in small pulmonary arteries. Both eNOS and nNOS are absent in the small pulmonary arteries of the adult sheep lung. In airways of fetal, newborn, and adult sheep, nNOS is found in the epithelium at all levels including the alveoli, whereas eNOS and iNOS are expressed primarily in proximal bronchiolar epithelia.

In addition to the NO produced by eNOS, iNOS, and nNOS in the pulmonary vessels and airways, high levels of NO can be produced by activation of iNOS in alveolar macrophages and cells recruited to the lung during inflammation. The adventitia of pulmonary vessels may provide a protective barrier by preventing the vasodilator effects of these extravascular sources of NO from influencing vessel tone. For example, NO produced locally within endothelial cells or applied to the luminal surface of pulmonary arteries is a potent vasodilator (Steinhorn *et al.*, 1994a). In contrast, application of NO to the adventitial surface has virtually no effect on pulmonary artery tone, whereas carbon monoxide and sodium nitroprusside are equipotent whether delivered to the endothelial or adventitial surface. These findings point to a highly localized regulation of pulmonary vascular tone by NO synthesized in the endothelium. The free radical nature of NO may be responsible for its localization by the adventitia, and this property may protect pulmonary vessels from high levels of NO produced by activation of iNOS in alveolar macrophages and inflammatory cells.

ONTOGENY OF THE NO PATHWAY

Nitric oxide synthase, soluble guanylate cyclase (sGC), and phosphodiesterase (PDE) all serve to modulate cGMP levels and smooth muscle tone in the pulmonary vasculature. The expression and activity of all three enzymes change during fetal and postnatal development (Fig. 3 vs. Fig. 7). A variety of methods have been employed to assess the level of activity in the NO–cGMP pathway during development including: (1) vascular responses to NOS inhibitors and to endothelium-dependent and independent dilators, (2) measurement of NO levels, and (3) measurement of protein and message for eNOS, sGC, and PDE.

Nitric Oxide Synthase NOS activity can be demonstrated early in the third trimester of gestation in the fetal lamb. In these preterm fetal lambs, inhibition of NOS increases PVR, indicating that basal PVR is modulated by endogenous NO (Kinsella *et al.*, 1994). Basal NO production in the lung increases by twofold later in gestation, and the endothelial-dependent agonists acetylcholine and oxygen demonstrate progressive pulmonary vasodilator potency during this developmental period in the fetal lamb (Lewis *et al.*, 1976). The pulmonary vasodilation to acetylcholine is blocked by NOS inhibitors and restored by excess L-arginine (Abman *et al.*, 1990; Tiktinsky *et al.*, 1992). NOS inhibition blocks virtually the entire increase in fetal pulmonary blood flow caused by oxygenation of the late-gestation fetal lamb (Fig. 4) (Tiktinsky and Morin, 1993). Inhibition of NOS

Figure 3 Diagram of the factors that favor high pulmonary vascular resistance during the early third trimester of fetal development. The size and density of labels and lines reflect relative concentrations and activity.

Figure 4 Effect of hyperbaric oxygenation on pulmonary blood flow in normal near-term fetal lambs (open squares). The dramatic increase in pulmonary blood flow is blocked by pretreatment with the NOS inhibitor *N*^G-nitro-L-arginine (L-NA). From Tiktinsky and Morin (1993), with permission.

immediately prior to delivery of the fetal lamb attenuates the increase in pulmonary blood flow and the decrease in PVR following birth (Abman *et al.*, 1990). Furthermore, chronic NOS inhibition in fetal lambs 10 days prior to birth similarly blunts the decrease in vascular tone and the increase in pulmonary blood flow normally seen at birth (Fineman *et al.*, 1994).

In contrast to the above findings, endothelial-independent agonists such as inhaled NO or the NO donor agent, sodium nitroprusside, produce greater changes in pulmonary blood flow than oxygen during early third trimester in the fetus (Abman and Accurso, 1991; Kinsella *et al.*, 1994). Infusion of *N*^G-nitro-L-arginine (L-NA) blocks the increase in pulmonary blood flow caused by oxygen but not inhaled NO. These findings indicate that the ability of the developing smooth muscle to respond to NO precedes the ability of the immature endothelium to increase and sustain the stimulated production and release of NO (Fig. 3).

Endothelial cell NOS (eNOS) protein and mRNA are detectable at 75% gestation and increase dramatically just prior to term in the fetal rat lung, thus optimizing the capacity for NO production at the time of birth (North *et al.*, 1994b). Immunostaining for eNOS is seen as early as 29% gestation in the fetal lamb lung, and peaks during mid-gestation (Halbower *et al.*, 1994). The mechanisms determining this pattern of expression are still not completely known, although estrogen appears to be quite important. Fetal circulating estrogen levels increase markedly during late gestation due to increasing placental production, surge just prior to birth, and subsequently fall. Fetal pulmonary arterial endothelial cells express estrogen receptors. Estrogen stimulates eNOS expression and activity in fetal pulmonary artery endothelial cells (Lantin-Hermoso *et al.*, 1997; MacRitchie *et al.*, 1997), and fetal plasma estrogen levels correlate well with the developmental changes in eNOS.

The vast majority of the previously mentioned studies on the regulation of pulmonary vascular resistance by NO have focused on the contribution of eNOS. More recently a role for iNOS and nNOS in modulating basal pulmonary vascular tone in the ovine fetus has been demonstrated (Rairigh *et al.*, 1998). In addition to the decrease in pulmonary vascular resistance at birth, the change from liquid breathing to air breathing also requires a marked decrease in lung liquid production. Nitric oxide decreases lung liquid production in fetal lambs (Cummings, 1997), and it is tempting to speculate that nNOS may be involved in this process due to its preferential distribution in alveoli, small airways, and small vessels.

Role of NOS in Hypoxic Vasoconstriction The capacity for hypoxic pulmonary vasoconstriction (HPV) is intrinsic to pulmonary vascular smooth muscle cells and is recognized as a primary mechanism for maintaining high pulmonary vascular tone in the fetus. Changes in nitric oxide synthase activity both directly and indirectly modulate hypoxic vasoconstriction. An acute decline in oxygen concentration depresses basal and acetylcholine-stimulated cGMP

production in pulmonary arteries from late gestation fetal lambs. This response to oxygen is absent in early third trimester (Shaul *et al.*, 1993), consistent with the developmental time course of fetal pulmonary vascular response to changes in oxygen tension described earlier. The activity and gene expression of nitric oxide synthase is reduced by hypoxia (McQuillan *et al.*, 1994; Shaul *et al.*, 1992). In addition, low oxygen tension (in part by NO-mediated mechanisms) induces the expression and secretion of the potent vasoconstrictor endothelin in cultured human endothelial cells (Kourembanas *et al.*, 1993).

Interaction between NO and Endothelin Endothelin-1 (ET-1) constricts pulmonary vascular smooth muscle by binding with high affinity to the ET_A receptors that are predominantly expressed in the smooth muscle cell layer. There appear to be two distinct subtypes of the ET_B receptor on pulmonary endothelial cells: the ET_{B1} vasodilator receptor and the ET_{B2} vasoconstrictor receptor (Perreault and Baribeau, 1995). All three receptors are present in the neonatal pulmonary circulation, and their expression increases with advancing gestation (Ivy *et al.*, 1998a). Nitric oxide appears to play a central role in endothelin-mediated vasodilation, as ET_{B1} receptor-mediated vasodilation is blocked by inhibition of nitric oxide synthase and hemoglobin (Zellers *et al.*, 1994).

The interaction between nitric oxide and endothelin is one likely mechanism responsible for the high PVR that occurs early in the third trimester of gestation (Fig. 3). ET-1 mRNA has been isolated from blood vessels within the perinatal lung (MacCumber *et al.*, 1989), and circulating immunoreactive ET-1 levels are very high in the fetal and transitional circulation (Kojima *et al.*, 1992) and decrease steadily in the postnatal period. Nitric oxide suppresses ET-1 synthesis (Kourembanas *et al.*, 1993), and cGMP inhibits ET-1-induced contraction and inositol phosphate production in fetal lamb pulmonary arteries (Millard *et al.*, 1998). Thus, decreased NO production by the endothelial cell during fetal life might contribute to high fetal PVR both by limiting vasodilation by stimulation of the endothelial receptor, and by allowing for increased production of ET-1 and inositol phosphate. Low oxygen tension, by decreasing nitric oxide production, induces the expression and secretion of ET-1 in cultured human endothelial cells (Kourembanas *et al.*, 1993). Nitric oxide also plays a role in the vascular response to endothelin. ET_A receptor blockade results in a dose-dependent increase in pulmonary blood flow, and selective ET_B agonists cause fetal pulmonary vasodilation (Ivy *et al.*, 1994, 1996). Both of these vasodilatory responses are blocked by inhibition of nitric oxide synthase.

Soluble Guanylate Cyclase Increases in NO lead to dilation of the pulmonary circulation by stimulating sGC and increasing cGMP concentrations in the cytosol of smooth muscle cells. The sGC enzyme in the pulmonary circulation is composed of $\alpha 1$, $\alpha 2$, and $\beta 1$ subunits. The abundance of the $\alpha 1$ subunit appears to correspond well with functional

responses to NO in the lung (Tzao *et al.*, 1998). Two heterodimers ($\alpha 1, \beta 1$ and $\alpha 2, \beta 1$) with no functional difference have been found in the human placenta (Russwurm *et al.*, 1998). Levels of $\alpha 1$ and $\beta 1$ subunits of sGC in the lungs of late-gestation and neonatal Sprague-Dawley rats are high. Similar to the pattern of expression for eNOS, sGC levels are high late in gestation, and are greater than those observed in the adult lung (Bloch *et al.*, 1997). Pulmonary sGC enzyme activity correlates well with its expression, and is approximately sevenfold greater in newborn rats compared to adult rats.

The generally accepted mechanism for NO-induced vessel dilation involves the sGC-catalyzed production of cGMP with subsequent activation of protein kinase G (PKG), leading to extrusion of calcium from the cell cytosol and relaxation. However, activation of PKG by cGMP does not appear to be important in the NO-dependent modulation of the response to hypoxia in the normotensive rat, or in modulation of the increased vascular tone in the hypertensive rat lung (Fouty *et al.*, 1998). The mechanism responsible for this PKG-independent relaxation is not known.

Phosphodiesterase PDE activity in the smooth muscle of pulmonary vessels regulates vessel tone by rapidly converting cGMP to the inactive metabolite GMP. Although multiple phosphodiesterase isoforms have been identified, PDE5 appears to be the dominant isoform in the lung. Immunohistochemistry and *in situ* hybridization have demonstrated PDE5 protein mRNA in vascular smooth muscle of neonatal sheep and rat lungs (Hanson *et al.*, 1998a; Sanchez *et al.*, 1998). PDE5 activity is apparent early in gestation and progressively increases until term.

PULMONARY ARTERIES VERSUS PULMONARY VEINS

The vast majority of studies on NO–cGMP signaling in the lung have concentrated on the arterial side of the pulmonary circulation. However, isolated pulmonary veins are much more responsive to both endothelium-dependent and -independent nitric oxide than are pulmonary arteries (Gao *et al.*, 1995; Steinhorn *et al.*, 1993). Developmentally, large pulmonary veins from fetal and newborn lambs produce more NO than do veins from older lambs. In contrast, both basal and stimulated release of NO from large pulmonary arteries increases during the first few weeks of life.

Immunostaining for sGC and PDE5 also reveals interesting differences between arteries and veins. Staining for sGC is intensely positive in pulmonary veins of fetal lambs, is positive in small pulmonary arteries, and virtually absent in large pulmonary arteries (D'Angelis *et al.*, 1998) (Fig. 5). The distribution pattern for PDE5 is the exact opposite in fetal lambs, and is greater in pulmonary arteries than veins (D'Angelis, unpublished observation). This distribution of PDE5 is supported by activity assays showing greater PDE5 activity in ovine pulmonary arteries versus veins (Okogbule-Wonodi *et al.*, 1998). The differential distribution patterns of sGC and PDE5 in arteries versus veins may have important functional consequences for pulmonary blood flow at birth.

Figure 5 Differential distribution of soluble guanylate cyclase (sGC) in larger pulmonary arteries (A), small pulmonary arteries (B), and pulmonary veins (C) of near-term fetal lambs. Magnification: (A) 180 \times , (B) 800 \times , (C) 90 \times .

The low sGC/high PDE5 pattern in pulmonary arteries would favor a phasic dilator effect of NO, whereas the high sGC/low PDE5 pattern in pulmonary veins would favor a more sustained tonic dilator effect of NO. Rapidly changing levels of cGMP in pulmonary arteries may endow them with the ability to respond quickly to changes in oxygen levels and shear stress and readjust blood flow to different regions of the lung. More stable levels of cGMP in pulmonary veins might favor a low and uniform vascular resistance downstream of pulmonary capillaries.

Summary

The NO–cGMP pathway for vessel dilation is primed for maximal activity and functional effectiveness at birth, because levels of eNOS and sGC peak near term and PDE5 levels decrease. These conditions provide an optimal environment for the pulmonary vasodilatory response to NO during transition when the lung is both ventilated and exposed to a higher oxygen tension than exists *in utero*.

The Transition at Birth

As the fetal pulmonary circulation develops, there are major changes in the expression of humoral factors that influence PVR resistance and prime the pulmonary circulation for transition to the extrauterine environment. The development of the NO–cGMP signaling pathway plays a major role in this transition.

At birth, PVR drops immediately and permits an 8- to 10-fold rise in pulmonary blood flow (Fig. 6). Simultaneously, systemic vascular resistance increases, due to removal of the low vascular resistance bed of the placenta. As pulmonary pressure falls to less than systemic pressure, pulmonary blood flow increases and blood flow through the patent ductus arteriosus reverses direction. Functional closure of the ductus occurs over the first several hours of life; largely in response to the increased oxygen tension. Left atrial pressure also increases leading to closure of the foramen ovale. These events establish the normal postnatal circulatory pattern of separate pulmonary and systemic circulations by effectively eliminating the fetal right-to-left shunts (Fig. 1B). Within 24 hours after birth, PA pressure decreases to approximately 50% of mean systemic arterial pressure and adult values are normally reached within 2 to 6 weeks (Rudolph, 1985). It is critical that all of the previously mentioned events occur within the first several hours of life in order for the normal postnatal pattern of circulation to be established.

Structural Adaptation to Extrauterine Life

Although there is no immediate postnatal reduction in the amount of vascular smooth muscle, structural adaptation rapidly occurs. Dilation and recruitment occur during the first 24 hours of life in the nonmuscular and partially muscular arteries of the precapillary bed. The external diameter

Figure 6 Changes in pulmonary hemodynamics during the last trimester of fetal life (to left of dashed line) and in the first days following birth (to right of dashed line).

of the nonmuscular arteries increases, and the prominent cuboidal endothelial cells seen in fetal life assume a flattened appearance. There is an increase in cell length and surface to volume ratio as the cells “spread” within the vessel wall to increase lumen diameter and lower resistance (Haworth *et al.*, 1987). The relative paucity of interstitial connective tissue at birth assists in this process by allowing for greater plasticity of the vessel. Dilation is followed by a reduction in muscularity, a process which begins in the first 24 hours of life and continues over subsequent weeks (Haworth, 1981). This overall reduction in muscularity further increases the lumen diameter, and functionally is associated with a reduction in the capacity of the PA to constrict with increasing age after birth. Through its antimitogenic effects, nitric oxide may be important in slowing replication of vascular smooth muscle cells and remodeling the pulmonary vasculature after birth.

Events that Initiate Transition

The stimuli that seem to be most important in decreasing PVR at birth are the rhythmic ventilation of the lungs with a gas and the increase in oxygen tension in the lungs. Each of these stimuli by itself will decrease PVR and increase pulmonary blood flow, but the largest effects are seen when the two events occur simultaneously (Teitel *et al.*, 1990). Studying the role of oxygenation independent of ventilation during transition is technically challenging. Chronically instrumented near-term fetal lambs have been studied while the ewe breathes oxygen in a hyperbaric chamber at three atmospheres. During hyperbaric oxygenation, fetal pulmonary vascular resistance decreases and pulmonary blood flow increases to levels comparable to after birth (Fig. 4).

Pulmonary endothelial cells play a central role in the pulmonary vascular transition through the production and release of numerous mediators that act on the subjacent smooth muscle cell layer. A complete discussion of their products is outside the scope of this chapter. However, the main endothelial products currently believed to be responsible for the pulmonary vasodilation at transition include arachidonic acid metabolites and nitric oxide. Prostacyclin (PGI₂) is the arachidonic acid metabolite most studied in the transition of the pulmonary circulation at birth. Prostacyclin may be important in pulmonary vasodilation following rhythmic distention of the lung, but does not appear to mediate the pulmonary vascular response to oxygenation in the fetus (Morin *et al.*, 1988). Despite a large body of research, the importance of prostacyclin in the transition at birth remains unclear.

Changes in NO–cGMP Signaling at Birth

Within 24 hours after birth, PA pressure decreases to approximately 50% of mean systemic arterial pressure (Fig. 6), and slowly declines to adult values within the next 2–6 weeks (Rudolph, 1985). The immediate increase in oxygen tension at birth alters the status of the smooth muscle and endothelial cells of the pulmonary vasculature (Fig. 7). One immediate effect of the increase in oxygen is reversal of the metabolic blockade of potassium channels in the smooth muscle cell layer leading to potassium efflux and a return of the membrane potential to the more polarized state typical in the adult pulmonary circulation. This closes voltage-dependent calcium channels leading to a decrease in cytosolic calcium, relaxation of pulmonary vessels, and a decrease in PVR.

After birth, eNOS abundance increases and peaks at 2–3 days. Subsequently, eNOS decreases in most vessels by 6 days and is nearly absent in the distal pulmonary arteries of adult animals (Halbower *et al.*, 1994; Hislop *et al.*, 1995). Despite the postnatal decrease of eNOS in small arteries, basal and stimulated production of NO from larger pulmonary arteries continues to increase after birth (Abman *et al.*, 1991; Steinhorn *et al.*, 1993).

The decrease in PVR is further augmented by a rapid increase in the oxygen-mediated availability of NO through

a variety of mechanisms. Inhibition of nitric oxide synthase blocks the pulmonary vascular response of the near-term fetal lamb to hyperbaric oxygenation (Fig. 4). Oxygen directly increases basal and acetylcholine-stimulated cGMP production in the pulmonary vasculature (Shaul *et al.*, 1992). Acute changes in oxygen tension do not produce similar changes in mesenteric arteries, suggesting that this dramatic effect of oxygen is due to a direct and specific effect on NO production by fetal pulmonary arteries (Shaul and Wells, 1994). The acute oxygen modulation of pulmonary endothelial NO production does not appear to be a result of production of a local receptor agonist, or changes in availability of oxygen or L-arginine as substrates for NOS. Oxygen may, however, directly effect NOS by altering pulmonary endothelial cell calcium homeostasis.

Oxygen also causes a rapid increase in red blood cell adenosine triphosphate (ATP). ATP or its metabolite adenosine cause pulmonary vasodilation in the fetus, a response that is blocked by inhibition of NOS (Konduri *et al.*, 1992; Steinhorn *et al.*, 1994b). ATP may stimulate endothelial NO production either by binding to purinergic receptors or directly to NOS. Plasma ATP levels increase in the pulmonary arteries of fetal lambs during ventilation with oxygen, and the decrease in PVR that accompanies ventilation with oxygen is abolished by blockade of adenosine and ATP receptors (Konduri *et al.*, 1993). Thus, increased synthesis and release of ATP may cause pulmonary vasodilation in response to birth-related stimuli in the ovine fetus.

The peptide bradykinin stimulates endothelial NO production, and is a potent pulmonary vasodilator in the fetus. Ventilating fetal lambs with oxygen, or exposing the fetus to hyperbaric oxygen, increases the blood concentrations of bradykinin (Heymann *et al.*, 1969). However, blockade of bradykinin receptors does not block the pulmonary vasodilation to oxygen (Banerjee *et al.*, 1994), and it is unknown whether a direct interaction between bradykinin and NO plays a role in the development of the response to oxygen.

Closure of the ductus arteriosus at birth and the decrease in PVR lead to a large increase in pulmonary blood flow. This increase in pulmonary blood flow increases shear stress in the pulmonary vasculature and activates signaling cascades in endothelial cells which produce and/or potentiate pulmonary vasodilation via increased synthesis and release of NO. An increase in shear stress increases eNOS mRNA and protein expression in lung tissue (Black *et al.*, 1997). Therefore, whenever a stimulus initiates an increase in pulmonary blood flow during transition, it increases shear stress and creates a positive feedback loop in which increased NO synthesis increases pulmonary blood flow still further. At least a portion of the pulmonary vasodilation that results from shear stress may be attributed to NO-mediated activation of K⁺-channels (Kv) in smooth muscle cells (Storme *et al.*, 1999).

The pattern of expression of soluble guanylate cyclase is similar to eNOS, with the highest levels of expression and activity noted in the first days following birth. Furthermore, within 1 hour following birth, PDE5 activity, protein, and mRNA dramatically decrease in newborn lamb and mouse

Figure 7 Diagram of the factors that favor low pulmonary vascular resistance at birth. The size and density of letters and lines reflect relative concentrations and activity.

lungs (Hanson *et al.*, 1998b). The low level of PDE5 activity following birth would be expected to enhance the effect of NO on pulmonary vascular smooth muscle by increasing cGMP levels in a manner that correlates well with the decrease in PVR early in transition.

regimens based on manipulation of the NO–cGMP pathway are discussed in the following sections.

Persistent Pulmonary Hypertension

Definition

The expected decrease in pulmonary vascular resistance and increase in pulmonary blood flow described earlier do not always occur normally during the transition to extrauterine life. Persistent pulmonary hypertension of the newborn (PPHN) is the result. This syndrome complicates more than 1 in 1000 live births and up to 10% of admissions to intensive care nurseries. There are no known genetic factors involved in its pathogenesis. Although it can occur in premature infants, PPHN is classically a disorder of the term infant.

PPHN is characterized by pulmonary hypertension causing right to left extrapulmonary shunting of blood and hypoxemia (Fig. 1C). It is a clinical syndrome rather than a specific disease, and is associated with a wide array of cardiac and respiratory disorders. PPHN may result when vasoconstriction of structurally normal pulmonary vessels

Summary of Developmental Changes Leading to Transition

Early in fetal life PVR is high due to relatively few pulmonary capillaries, high vascular smooth muscle tone induced by hypoxia and endothelin, and a poorly developed NO–cGMP signaling pathway (Fig. 3). As lung development progresses toward term, the NO–cGMP pathway matures such that, at birth, it assumes a major role in the transition of the pulmonary circulation to a high flow/low pressure circuit (Fig. 7). Abnormalities in fetal lung development can interrupt maturation of the NO–cGMP pathway at several sites and interfere with this transition. The lack of a properly functioning NO–cGMP pathway for inhibition of pulmonary vascular tone at birth is a major contributing factor to the development of PPHN. The causes of PPHN, animal models for investigating this disease, and therapeutic

occurs in response to acute asphyxia, or alveolar hypoxia due to parenchymal disorders such as hyaline membrane disease or meconium aspiration syndrome. However PPHN can occur idiopathically in the absence of underlying parenchymal disease. It is believed that in these cases, the syndrome is the result of an abnormal remodeled vasculature that develops *in utero* in response to prolonged fetal stress, hypoxia, and pulmonary hypertension. PPHN causes substantial morbidity and mortality in otherwise normal term infants. Clinically, once recovery occurs, neurologic sequelae are a concern. Although there are theoretical concerns that an early insult may “imprint” the vasculature unfavorably, clinical outcome studies do not currently indicate that pulmonary hypertension recurs later in life.

Presently, over 1000 infants per year with PPHN require transport to specialized centers that provide extended heart lung bypass, known as extracorporeal membrane oxygenation or ECMO. Although ECMO is life-saving, it is expensive, invasive, and carries a substantial risk of morbidity. By design, cardiopulmonary bypass will decrease pulmonary blood flow and pressure and therefore may indirectly benefit the pulmonary vasculature. However it is not specific therapy designed to reverse PPHN. Therefore, understanding the role of mediators such as nitric oxide in the abnormal transition is important. This understanding should lead to development of safer, more effective therapies for PPHN and ultimately its prevention.

Human Studies

It is difficult to measure endogenous nitric oxide production in the newborn infant, and direct assay of NO production by pulmonary endothelial cells is not currently feasible. Therefore, the few studies in human infants have all been based on more global measures of nitric oxide production. Urinary nitrites and nitrates are lower in infants with PPHN than in healthy term infants (Dollberg *et al.*, 1995). Plasma cGMP concentrations are also low, and increase rapidly in response to inhaled NO (Christou *et al.*, 1997). More recently, eNOS expression was found to be absent in umbilical vein endothelial cells cultured from four out of six infants who subsequently developed PPHN (Villaneuva *et al.*, 1998). Taken together, these studies provide indirect evidence for a deficiency of endogenous NO production in infants with PPHN. However, it is impossible to determine whether the absence of eNOS is the cause of PPHN, or whether PPHN leads to a loss of eNOS.

Effects of NO Synthase Inhibition or Disruption

Does a decrease in endogenous NOS activity produce clinical PPHN? Acute or chronic infusions of the nonspecific NO synthase inhibitor, L-NA, in fetal lambs produce physiological abnormalities consistent with PPHN following delivery (Abman *et al.*, 1990; Fineman *et al.*, 1994). Pulmonary arterial pressure and pulmonary vascular resistance are increased relative to control lambs, and hypoxemia re-

sults due to shunting of deoxygenated blood across the foramen ovale. These lambs are fully responsive to inhaled nitric oxide and nitric oxide donor agents, and following birth their pulmonary hypertension can be completely reversed with L-arginine. These findings suggest that inhibition or decreased activity of NOS could cause acute PPHN in some infants. Of particular interest is that persistent pulmonary hypertension develops in these lambs *without* associated pulmonary vascular remodeling. Therefore, reduction of endogenous NO production alone is probably not sufficient to produce the full physiological and anatomic picture of PPHN.

Mice with targeted disruption of endothelial or neuronal NOS offer an alternative experimental approach to infusions of pharmacological inhibitors, although measurements of pulmonary hemodynamics are technically challenging in adult animals, and currently not feasible in the newborn. Disruption of endothelial or neuronal NOS expression does not increase perinatal mortality. Adult eNOS $-/-$ mice have at most a modest increase in pulmonary vascular resistance in a baseline unstressed state, but exhibit a striking exaggerated physiological response and increase in muscularization in peripheral arterioles in response to even mild hypoxia (Fagan *et al.*, 1999; Steudel *et al.*, 1998). Interestingly, even a 50% reduction of eNOS protein results in augmentation of the pulmonary vascular sensitivity to hypoxia.

Effect of PPHN on NO–cGMP Signaling

Most studies have addressed the converse of the previous question: Is PPHN associated with alterations in NOS expression and/or activity? Similar to the problem in evaluating the human studies, it must be kept in mind that it is difficult to differentiate whether alterations in specific enzymes are responsible for producing PPHN, or occur in response to it. Still, important insights into pathophysiology and therapeutic options can be gained from the study of animal models of PPHN.

PRENATAL DEVELOPMENT OF PULMONARY VASCULAR ABNORMALITIES

Newborns who die due to idiopathic persistent pulmonary hypertension of the newborn display an increase in pulmonary arterial medial smooth muscle and extension of muscle to normally nonmuscular pulmonary arteries (Haworth and Reid, 1976; Murphy *et al.*, 1981). The muscle cells are frequently surrounded by heavy elastic laminae, suggesting they formed several weeks before death. Further, these anatomic changes are observed in infants dying in the first 24 hours of life, which strongly suggests that an altered intrauterine environment may produce structural changes in the pulmonary circulation of the fetus.

To study the antenatal development of PPHN, intrauterine models of persistent pulmonary hypertension have been developed in the fetal lamb. The relatively large size of the fetal lamb makes it suitable for surgical intervention and physiological study as a fetus and immediate newborn. Fur-

thermore, the ewes tolerate uterine surgical intervention well, and are relatively resistant to premature labor.

Ductal Constriction or Ligation In the normal fetus, diversion of right ventricular output away from the lungs across the ductus arteriosus may be an important mechanism that protects against remodeling of pulmonary resistance arteries. PPHN is more common in postterm newborns, which may be due to intrauterine constriction of the fetal ductus arteriosus. A rare cause of PPHN in infants is prenatal constriction of the ductus arteriosus due to maternal ingestion of prostaglandin synthesis inhibitors. The most common model currently in use for the study of PPHN is the ductal ligation model.

Following surgical constriction of the ductus arteriosus, pulmonary blood flow acutely increases. However, within 2 hours pulmonary blood flow decreases back to baseline while pulmonary vascular resistance remains high. Fetal lambs born 7 to 14 days following ductal constriction or ligation have persistent pulmonary hypertension (Abman *et al.*, 1989; Morin, 1989), with all the physiological hallmarks of the human syndrome, including pulmonary arterial pressure equal to aortic pressure and hypoxemia unresponsive to ventilation with 100% oxygen. Structural alterations also occur, including extension of smooth muscle into the normally nonmuscular distal arteries and the formation of periadventitial fibrosis surrounding the intraacinar arteries (Wild *et al.*, 1989) (Fig. 8). These changes are identical to those observed in human infants.

Activity, message, and protein content of endothelial nitric oxide synthase are decreased by approximately 50% in lung extracts of ligated compared to control fetal lambs (Black *et al.*, 1998a; Shaul *et al.*, 1997; Villamor *et al.*, 1997). Preliminary studies indicate that neuronal NOS expression in the peripheral arterioles is also decreased (Tzao *et al.*, 1999). The pulmonary vasculature of ductal ligation lambs dilates in response to nitric oxide inhalation, but high concentrations are required to decrease pulmonary arterial pressure and pulmonary vascular resistance to near normal levels. This may be due in part to increased production of potent competing vasoconstrictors such as endothelin-1. However, this response pattern to exogenous NO can also be explained by other alterations in the nitric oxide–cGMP pathway as described later.

Relaxations to atrial natriuretic peptide and cGMP analogs are similar in control and hypertensive lambs, indicating that the remodeled pulmonary vessels relax normally when cGMP concentrations increase sufficiently. However, in addition to decreased endothelial NO synthase content and activity, soluble guanylyl cyclase content and activity are decreased. Pulmonary arteries isolated from PPHN lambs have diminished relaxations and cGMP accumulation in response to sodium nitroprusside and nitric oxide gas compared to controls (Steinhorn *et al.*, 1995). Protein contents for both the α and β subunits of soluble guanylate cyclase are decreased (Black *et al.*, 1998a; Tzao *et al.*, 1998), and immunostaining localizes the decrease in sGC expression to

all levels of the arterial tree, with the most striking changes in the smallest resistance arterioles. Cyclic GMP specific phosphodiesterase activity appears to be elevated in PPHN lambs, by a mechanism that may involve posttranslational modification by phosphorylation. Increased phosphodiesterase activity would further depress the already decreased cGMP concentrations in response to endogenous and exogenous NO.

Abnormal Lung Growth Congenital diaphragmatic hernia (CDH) occurs when the diaphragmatic leaflets fail to fuse early in gestation, allowing the bowel to migrate into the chest cavity. Pulmonary hypoplasia occurs to a variable degree, probably in proportion to the volume and duration of intestinal herniation. In lung development, the vessels develop in parallel with the conducting airways. As a result, the pulmonary vascular bed in CDH is reduced in proportion to the degree of pulmonary hypoplasia, and abnormal muscularization of arterioles occurs as described earlier (Bohn *et al.*, 1987). Even with advanced support techniques such as ECMO, mortality has remained nearly 50%.

CDH can be induced in approximately 50% of rat fetuses after maternal ingestion of the herbicide nitrofen early in gestation. In this model, eNOS mRNA and protein abundance are decreased in the lung ipsilateral to the hernia compared to lungs from unaffected littermates. Congenital diaphragmatic hernia can also be surgically produced in the second trimester in the fetal lamb. Physiological and anatomic findings are similar to that seen in severely affected human infants. In this model, NO synthase content and functional activity are not altered in large pulmonary arteries (Karamanoukian *et al.*, 1995). However, NO synthase activity is abnormal in pulmonary veins, with the most striking abnormalities observed in veins isolated from the smaller lung ipsilateral to the hernia (Irish *et al.*, 1998). Relaxations to NO donor agents are normal in both pulmonary arteries and veins, indicating that at least prior to birth the vascular smooth muscle responds normally to NO. However, as described later, even when there is an initial dramatic improvement in oxygenation, infants with CDH are less likely to sustain a response to inhaled NO.

POSTNATAL DEVELOPMENT OF PULMONARY VASCULAR ABNORMALITIES

Hypoxic Vasoconstriction The development of acute vasoconstriction and chronic hypertension in response to hypoxia is a key feature that distinguishes the pulmonary circulation from the systemic circulation. In newborn and adult animals, acute hypoxia produces a prompt rise in pulmonary artery pressure and pulmonary vascular resistance. However, hypoxic vasoconstriction appears to be attenuated in the early newborn period, and increases strikingly with postnatal age (Fike and Hansen, 1987). This attenuation correlates well with the rapid alterations in NO–cGMP signaling that occur at birth and favor sustained increased cGMP concentrations and pulmonary vasodilation. The site of hypoxic vasoconstriction also varies with postnatal age. In contrast

Figure 8 Example of pulmonary arterioles from normal near-term fetal lambs (A) and from lambs with PPHN following ductal ligation (B). In PPHN, the arterioles have a muscularized arterial wall, double elastic lamina (arrows), and adventitial proliferation. From Wild *et al.* (1989), with permission.

to adult lungs, in which the pulmonary arteries are the major site of hypoxic vasoconstriction, both pulmonary arterial and small diameter venous pressures increase following acute hypoxia in newborn lambs and piglets (Fike and Kaplowitz, 1992; Raj and Chen, 1986).

The role of NO synthase in modulating acute hypoxic pulmonary vasoconstriction remains controversial. Nitric oxide synthase inhibitors potentiate hypoxic vasoconstriction in newborn piglets and lambs (Gordon and Tod, 1993), suggesting that endogenous NO production may attenuate hypoxic vasoconstriction. However other studies demonstrate that decreased oxygen tension inhibits NO synthase expression and activity in fetal lambs (North *et al.*, 1996; Shaul *et al.*, 1992), and exhaled NO and NO metabolites fall during acute hypoxia in perfused lungs isolated from newborn piglets (Nelin *et al.*, 1996). Studies examining the newborn response to hypoxia following knockout of the NOS gene would be helpful, but have not been done because of the technical challenges.

Chronic Hypoxia Prolonged hypoxia following birth is an important cause of PPHN, and a widely used model for

its study. Neonatal pulmonary vascular smooth muscle cells respond to hypoxia with a more vigorous proliferative response than adult cells, leading rapidly to structural changes. The vasculature of newborn piglets exposed to 72 hours of hypoxia from the moment of birth retains a fetal shape and spacial relationship, and the vascular smooth muscle cells retain a fetal phenotype (Haworth, 1988). In addition to retaining the fetal potential for smooth muscle cell proliferation, there is enhanced accumulation of extracellular matrix connective tissue components.

Important functional changes in NO-mediated relaxations accompany these structural changes. Endothelial nitric oxide synthase expression and activity are decreased in newborn animals exposed to chronic hypoxia (Fike *et al.*, 1998; Hislop *et al.*, 1997; Orton *et al.*, 1988). This is in contrast to the multiple studies indicating that in adult rats, prolonged hypoxia *enhances* expression of NOS (Lecras *et al.*, 1996; Shaul *et al.*, 1995), and that this upregulation occurs precisely at the onset of vascular remodeling (Xue and Johns, 1996). Further investigation will help delineate whether these opposite findings represent important development differences in NO synthase function, or whether chronic hy-

poxia produces alterations in the nitric oxide target enzyme pathways in the vascular smooth muscle cell which decrease sensitivity to endogenous and exogenous NO.

Alterations in smooth muscle response to NO may occur following chronic hypoxia. Relaxations and cGMP accumulation in response to both endogenous and exogenous NO are blunted following 7 days of hypoxia in adult rats, but responses to atrial natriuretic peptide (ANP) remain equivalent to controls (Crawley *et al.*, 1992). Rodman (1992), found that relaxations to endogenous NO, exogenous NO, and cGMP were all blunted in pulmonary arteries isolated from rats exposed to 35 days of hypoxia. Taken as a whole, these data indicate that in chronic hypoxia, defects in relaxation may develop over time, first at the level of the endothelium, followed by soluble guanylyl cyclase, followed by alterations in smooth muscle response to cGMP. Even briefer periods of hypoxia disrupt responses to exogenous nitric oxide in newborn piglets, indicating increased sensitivity to hypoxia during the early newborn period (Tulloh *et al.*, 1997).

Congenital Heart Disease Pulmonary hypertension commonly develops in infants with congenital heart lesions that are associated with increased pulmonary blood flow, such as truncus arteriosus or atrioventricular canal. If the heart lesion is not corrected, vascular changes of medial and intimal thickening occur, which ultimately lead to luminal obliteration. The obvious differences in pulmonary hypertension induced by a chronic increase in pulmonary blood flow from that induced by hypoxia has led to the development of specific animal models. As described earlier, increases in shear stress stimulate endothelial cells to produce several modulators of vascular tone, including NO. Large aortopulmonary shunts have been successfully placed in the late gestation ovine fetus, producing a model with the greatest similarity to children with congenital heart disease (Reddy *et al.*, 1995). At 1 month of age, the ratio of pulmonary to systemic blood flow is approximately 2 to 1; and while pulmonary vascular resistance is low after birth, it rises to near systemic values by 4 to 6 weeks of age. Morphological changes occur at this time, characterized by extension of muscle into small peripheral arteries, medial hypertrophy of small muscular arteries, and an increase in the total number of vessels (Reddy *et al.*, 1995).

High pulmonary blood flow from these shunts produces complex functional alterations in NO-mediated vasodilation. While endothelium-dependent vasodilation is decreased in 4 week old lambs, pulmonary vascular constriction to blockade of nitric oxide synthase is enhanced and plasma concentrations of cGMP are high (Reddy *et al.*, 1996). Expression of eNOS, the α and β subunits of soluble guanylyl cyclase, and Type 5 phosphodiesterase are all increased in lung parenchyma from shunted lambs, and *in situ* hybridization and immunohistochemistry localized the increase in eNOS to the endothelium of small and large pulmonary arteries (Black *et al.*, 1998b). These changes in NO–cGMP signaling are an interesting contrast to the changes observed in the ductal

ligation model, indicating that pressure and flow may induce different abnormalities in endothelium–smooth muscle signaling.

Pulmonary hypertension can be dramatically exacerbated following cardiopulmonary bypass even in very young infants. Microemboli, neutrophil activation and sequestration, interruption of normal pulmonary blood flow, excessive thromboxane production, hypoxic vasoconstriction, and platelet adhesion all occur, and may disrupt endothelial function. If the endothelium is producing large amounts of NO prior to bypass, it is easy to envision that its disruption following bypass could shift the balance toward vasoconstrictors such as endothelin.

Clinical Importance of the NO–cGMP Pathway in PPHN

RESULTS OF CLINICAL TRIALS

To restore the normal transition in infants with PPHN, a vasodilator selective for the pulmonary circulation is needed. Nitric oxide is a gas, which allows it to be delivered directly to the lung. Further, the systemic circulation is protected because NO is rapidly inactivated by its combination with hemoglobin, forming nitrosohemoglobin and subsequently methemoglobin. Initial studies in animal models and human infants showed that NO inhaled at doses between 5 and 80 ppm improved systemic oxygenation in newborns with persistent pulmonary hypertension without decreasing systemic blood pressure. The animal studies further showed that inhalation of 80 ppm NO for 24 hours did not increase lung injury.

The clinical applications of inhaled NO have been studied in a wide range of populations and disease states, but to date the results are most compelling in the hypoxic newborn with PPHN. In two multicenter, randomized, placebo-controlled studies of term infants with PPHN (Table I), inhaled NO significantly improved systemic oxygenation and decreased the need for ECMO by approximately 30% (Neonatal Inhaled Nitric Oxide Study Group, 1997a; Roberts *et al.*, 1997). Although they report similar results (Fig. 9), the two studies used different concentrations of NO and enrolled quite different populations of infants. For example, although both studies enrolled infants with hypoxemia, documentation of pulmonary hypertension was only required for entry in the Roberts *et al.* (1997) trial. The similar outcomes in the two different patient populations may indicate that the clinical response to NO is not completely determined by the underlying disease state. A third large multicenter trial of NO inhalation studied patients earlier in the course of PPHN, and found a reduction in ECMO use similar to the two previous studies (Davidson *et al.*, 1998). However, *no* study has shown that NO reduces the incidence of death, neurologic sequelae, or chronic lung disease, findings that have been attributed to the availability and efficacy of ECMO. Although inhaled NO is an extraordinary advance in the therapeutic approach to PPHN, these studies clearly demonstrate that NO is not universally effective.

Table I Characteristics of Multicenter, Randomized, Placebo-Controlled Clinical Trials of Inhaled NO for PPHN

Authors	N	Entry criteria	Initial NO dose	Other therapies	Outcome measure
NINOS (1997a)	235	OI > 25 × 2, ≥34 weeks, ≤14 days old	20 ppm, may increase to 80 ppm	HFV permitted (55%), surfactant permitted (72%)	Death, ECMO
Roberts <i>et al.</i> (1997)	58	PPHN, ≥37 weeks, PaO ₂ < 55	80 ppm	No HFV, surfactant permitted	Oxygenation (PaO ₂ > 55)
Davidson <i>et al.</i> (1998)	155	PPHN, ≤72 hours old, >37 weeks, PaO ₂ > 40 < 100	5, 20, or 80 ppm	No HFV, no surfactant	Death, ECMO, adverse sequelae

OI, oxygenation index; HFV, high frequency ventilation.

The correct clinical dose of inhaled NO is controversial. Animal studies, which allow for direct measurement of hemodynamics, indicate that pulmonary vascular resistance decreases in a dose-dependent fashion. However, in clinical studies, oxygenation and clinical efficacy were not different whether NO was inhaled at doses of 5, 20, or 80 ppm (Davidson *et al.*, 1998). Potential toxicities of NO are important in considering the ideal NO dose. NO is clinically delivered in combination with high concentrations of oxygen. This may favor the oxidation of NO to nitrogen dioxide, which even in very low concentrations can acutely injure the distal airways and alveoli, and disrupt the vascular endothelium. Furthermore, there may be increased production of superoxide due to inflammatory lung disease and high inspired oxygen concentrations. When NO comes into contact with superoxide, peroxynitrites are formed that may damage surfactant associated proteins, inhibit surfactant function, and cause cell damage. Another concern is that nitrosyl-hemoglobins formed when NO combines with hemoglobin are oxidized to methemoglobin. The balance of methemoglobin will depend on its rate of production, and the rate of elimination by methemoglobin reductase in the erythrocyte, an enzyme which has reduced activity in the newborn period.

Significant increases in methemoglobin (> 7% of total hemoglobin) occur commonly during delivery of doses of 80 ppm to newborns. Finally, nitric oxide increases cGMP concentrations in platelets as well as in vascular smooth muscle, which can inhibit platelet aggregation and adhesion. NO inhalation increases bleeding time in healthy adult humans by 30%, and initial clinical trials indicate that premature infants treated with inhaled NO may have a very high incidence of intracranial hemorrhage.

CONGENITAL DIAPHRAGMATIC HERNIA:

A UNIQUE SUBSET OF PATIENTS

Because of its unique pathophysiology, all of the previously mentioned clinical studies using inhaled NO specifically excluded infants with congenital diaphragmatic hernia. A multicenter trial enrolling only infants with CDH showed a significant *increase* in ECMO use following NO treatment, indicating that nitric oxide affects the hypoplastic lung adversely (Neonatal Inhaled Nitric Oxide Study Group, 1997b). The reason for this adverse effect is not clear. In some cases it may be due to poor lung recruitment due to surfactant deficiency. It is also likely that the hypoplastic pulmonary vasculature allows for sustained postnatal pul-

Figure 9 Comparison of results of two major clinical trials (NINOS, 1997a; Roberts *et al.*, 1997) of NO inhalation in infants with PPHN.

monary hypertension when pulmonary blood flow increases, subsequently leading to rapid vascular remodeling and decreased vascular smooth muscle responsiveness to NO. Infants with hypoplastic lungs who are initially refractory to inhaled NO do respond after a period of ECMO support (Karamanoukian *et al.*, 1994). This could result from improved lung recruitment due to restored surfactant synthesis, or possibly due to protection and recovery of the pulmonary vasculature during ECMO support.

CLINICAL PROBLEMS ENCOUNTERED USING NO

Inhaled NO is clearly not universally effective. In some cases, this may be due to lack of delivery to the target site. It is widely presumed that when NO is delivered as an inhaled gas, its small molecular weight allows it to simply diffuse through the pulmonary interstitium and vascular adventitia into the vascular smooth muscle cell. As discussed earlier, in reality, nitric oxide does not readily cross the adventitia of pulmonary vessels (Steinhorn *et al.*, 1994a). The clinical implication is that nitric oxide must be delivered to peripheral lung units to be effective, which can be difficult when parenchymal lung disease is present.

The clinical response to NO is more heterogeneous than can be explained by lack of effective delivery to the lung periphery. Even a dramatic initial response to NO is often transient. To further complicate clinical use of NO, life-threatening rebound pulmonary hypertension may occur when NO is discontinued after only a few hours of inhalation (Miller *et al.*, 1995). Rebound pulmonary hypertension occurs even if the initial response to inhaled NO was modest, and may leave the patient in worse condition than prior to initiation of NO. It is attractive to theorize that decreased expression of endothelial NOS in response to exogenous NO is responsible for this response. NO donor agents acutely alter NOS activity, but do not alter eNOS expression in pulmonary artery endothelial cell cultures (Sheehy *et al.*, 1998). Chronic administration of NO downregulates soluble guanylyl cyclase activity in pulmonary vascular smooth muscle cells, indicating that the vascular smooth muscle cell may also alter its response to NO during prolonged exposures.

ENHANCEMENT OF NO EFFECT

Because NO must be delivered to peripheral lung units, clinical strategies designed to improve lung recruitment become critical components of successful therapy. Studies delivering inhaled nitric oxide in combination with high frequency oscillatory ventilation or exogenous surfactant indicate that these strategies may enhance the clinical efficacy of nitric oxide. Ventilation with oxygen-carrying perfluorochemicals is an exciting new experimental strategy that may improve lung recruitment in the face of severe surfactant deficiency or inactivation. Preliminary data indicate that the pharmacokinetics of inhaled nitric oxide are similar whether it is delivered to the perfluorocarbon-filled or the conventionally gas-ventilated lung. The combination of these two therapies may therefore represent an additional way to deliver nitric oxide in the face of severe parenchymal lung disease.

Lung recruitment does not provide the whole answer to this clinical problem. It is important to note that the clinical efficacy of NO in the NINOS trial, which allowed use of lung recruitment strategies such as surfactant and high frequency ventilation, was not different than the Roberts *et al.* (1997) trial which restricted access to these therapies. After vascular injury, the adventitia, as well as the vascular smooth muscle cell, are sites of cellular proliferation in both animal models and human infants with PPHN. New reports indicate that the adventitia is metabolically active and produces superoxide. Furthermore, exogenous NO may induce superoxide formation in endothelial and other cells (Munzel *et al.*, 1995; Sheehy *et al.*, 1998). The relative intracellular activities of superoxide and superoxide dismutase (SOD) provide a potential pathway for modulating the effects of nitric oxide in the lung (Fig. 10). By reducing NO clearance by superoxide, SOD significantly enhances responses to nitric oxide *in vitro* (Cherry *et al.*, 1990). A newly developed recombinant human Cu,Zn-SOD is being tested in infants at high risk for lung injury. Experimental studies indicate that SOD in conjunction with nitric oxide may decrease oxidative lung injury and enhance the physiological effects of inhaled nitric oxide (Davis, 1998).

Similar to the animal models described earlier, some patients may not sustain a response to nitric oxide due to

Figure 10 Diagram of potential points of the NO-cGMP signaling pathway that may allow for therapeutic intervention and enhancement of effect.

abnormalities of vascular development or function. This may be due to altered content or activity of soluble guanylyl cyclase or the cGMP phosphodiesterase isoenzyme. If so, inhibition of cGMP phosphodiesterase activity may provide an avenue for increasing efficacy of inhaled nitric oxide in human infants with PPHN by increasing cGMP concentrations (Fig. 9). Dipyridamole, which has been used for many years in humans, has significant inhibitory activity against cGMP phosphodiesterase. Dipyridamole augments the pulmonary vascular response to inhaled NO in adult patients with pulmonary hypertension following cardiopulmonary bypass (Fullerton *et al.*, 1997), and in some pediatric patients with pulmonary hypertension (Ziegler *et al.*, 1998). Dipyridamole may also prevent rebound pulmonary hypertension when inhaled NO is withdrawn (Ivy *et al.*, 1998b), and thereby allow for safer transport of infants who fail to respond to inhaled NO. There is little experience to date with its use in human infants. Dipyridamole selectively dilates the pulmonary circulation in the ovine fetus by augmenting the response to endogenous NO production (Ziegler *et al.*, 1995). However, dipyridamole inhibits other phosphodiesterase isoforms involved in cAMP metabolism, and its use must be approached with caution in the newborn period. In newborn lambs with PPHN, dipyridamole decreased pulmonary vascular resistance, but produced marked systemic hypotension at the same time (Dukarm *et al.*, 1998). Although the use of lower dipyridamole doses avoided systemic hypotension, they did not enhance the effect of inhaled NO.

Experimental pharmacological inhibitors such as zaprinast (M&B 22,948) and E4021 have more recently been developed for the Type 5 phosphodiesterase, and may be more potent and selective than dipyridamole. When zaprinast is administered in combination with a threshold dose of inhaled NO (6 ppm) in the ductal ligation lamb model, the drop in pulmonary vascular resistance and increase in oxygenation are quadrupled compared to nitric oxide alone (Thusu *et al.*, 1995). The combination of zaprinast and NO also significantly increases the duration of vasodilation to inhaled NO (Ichinose *et al.*, 1995).

If selective enough, phosphodiesterase inhibition may be effective even *without* the use of exogenous NO. For example, E4021, an experimental agent, is 100 times as potent as zaprinast for PDE5 (Saeki *et al.*, 1995), and has minimal to no inhibitory activity for other PDE isoenzymes. In newborn lambs with PPHN, increasing doses of E4021 result in selective pulmonary vasodilation without systemic hypotension. Using this strategy, a pulmonary vascular response equivalent to 50–100 ppm inhaled NO is possible by using E4021 alone.

Summary

Persistent pulmonary hypertension of the newborn is a syndrome that results from stresses on the pulmonary vasculature during critical developmental periods before or just after birth. Alterations in NO production and NO–cGMP signaling are clearly associated with PPHN, although it is

not as clear whether they directly produce PPHN. Inhaled NO is now widely used to increase pulmonary blood flow and correct hypoxia in newborns with PPHN, but the clinical response is often absent or not sustained. Other methods to increase cGMP concentrations, such as inhibition of superoxide or cGMP-specific phosphodiesterase (PDE5), may enhance the response to inhaled NO and allow more infants to respond, to respond to lower concentrations of NO, and to sustain their response.

endothelial nitric oxide synthase gene therapy, 536
features, 515
inducible nitric oxide synthase gene therapy, 516–517, 535
nitric oxide
 adverse effects, 515–516
 protective effects, 516, 536
 pathogenesis, 515
Tricyclic antidepressants, nitric oxide in analgesia, 888–889
Troglitazone, effects on nitric oxide synthase expression, 803

U

Uremia, platelet dysfunction, 833
Uric acid, peroxynitrite scavenging, 347
Uveitis, inducible nitric oxide synthase knockout mouse, 859

V

Vascular endothelial growth factor (VEGF), nitric oxide release response, 765
Vascular smooth muscle cell (VSMC)
 cyclic AMP effects on growth, 417
 cyclic GMP-dependent protein kinase modulation
 effects on gene expression, 416
 expression, 415–416
 growth, 416–417
 mitogen activated protein kinase effects, 417–418
 membrane potential, potassium channels
 activation by endothelium-derived hyperpolarizing factor, 571–572
 types, 570–571
 phenotypic modulation, 414–416
 vascular injury response, 512–513
Vasodilator-associated phosphoprotein (VASP)
 cyclic GMP-dependent protein kinase phosphorylation, 412
 nitric oxide–cyclic GMP signal transduction pathway, 16
Vasomotion, nitric oxide effects, 488–489
VASP, *see* Vasodilator-associated phosphoprotein

VEGF, *see* Vascular endothelial growth factor
Vein, nitric oxide effects, 922–923
Vein graft intimal hyperplasia
 endothelial nitric oxide synthase gene transfer, 514–515, 535
 pathophysiology, 514
Venule, nitric oxide effects, 923
Viral infection
 antiviral actions of nitric oxide, 736–737
 mutagenic potential of nitric oxide-derived metabolites, 740
 overproduction of nitric oxide, 735–737
Viral infection, carcinogenesis, 915–917
VSMC, *see* Vascular smooth muscle cell

W

Wound healing
 inducible nitric oxide synthase gene therapy, 517–518, 538
 nitric oxide role, 538

X

Xanthine oxidase, reactive oxygen species production, 281

Y

Y⁺
 regulation of nitric oxide synthesis, 194–195, 235
 regulators of activity, 227
YC-1, guanylate cyclase inhibition, 376–377, 396

Z

Zinc tetrathiolate center
 destruction by nitric oxide, 819–820
 nitric oxide synthase
 disulfide substitution, 101–102
 site-directed mutagenesis studies, 100
 stoichiometry, 99–100
 structural effects of zinc binding, 100–101
